ABSTRACT
Decayless kink oscillations of an ensemble of loops are captured simultaneously by the High Resolution Imager (HRI) of the Extreme Ultraviolet Imager (EUI) and the Atmospheric Imaging Assembly (AIA) from 22:58 UT on 5 November to 00:27 UT on 6 November 2021. Oscillations are analysed by processing image sequences taken by the two instruments with a motion magnification technique. The analysed loops are around 51 Mm in length, and oscillate with short periods of 1–3 min (1.6 min in average) and displacement amplitudes of 27–83 km. The signals recorded by AIA are delayed by 66 s as compared to HRI, which coincides with the light travel time difference from the Sun to each instrument. After correction of this time difference, the cross-correlation coefficient between the signals from the two data varies from 0.82 to 0.97, indicating that they are well consistent. This work confirms that HRI sees the same oscillations as AIA, which is the necessary first step before proceeding to the detection of shorter time scales by EUI. In addition, our results indicate the robustness of the de-jittering procedure in the study of kink oscillations with HRI.

Key words: Sun: corona – Sun: oscillations – waves

1 INTRODUCTION
Oscillatory and wave phenomena detected in the solar corona are subject to intensive study mainly in the context of their possible relevance to the long-standing problem of coronal plasma heating (e.g. ?) and because of their plasma diagnostics potential (e.g. ?). A puzzling class of coronal oscillations are the omnipresent low-amplitude decayless kink oscillations of coronal loops, appearing as repetitive displacements of the loops in the plane of the sky (?) or as persistent Doppler shift oscillations of coronal emission lines (?). The oscillation periods have been found to range from 1.5 to 10 min, and scale linearly with the loop length (?). The latter finding indicates that the oscillations are standing kink modes. The average apparent displacement amplitude in the plane of the sky is 0.17 Mm, i.e., smaller than the pixel size of available coronal EUV imagers.

The main interest in decayless kink oscillations is connected with their ubiquity. In particular, the oscillations are seen to occur without any association with energy releases such as flows or eruptions. It allows one to use them for seismological diagnostics of coronal loops and active regions during quiet times (?), i.e., before flares and eruptions. The simultaneous detection of the fundamental and second parallel (axial) harmonics (?) opened up a possibility to study the field-aligned structure of the equilibrium plasma parameters in the oscillating loop (e.g. ??). In addition, revealing the mechanism for the compensation of the oscillation damping may shed light on the energy balance in active regions.

Several mechanisms responsible for the existence of decayless kink oscillations have been proposed. ? ruled out their excitation by monochromatic drivers such as p-modes or chromospheric oscillations. Concerning non-monochromatic mechanisms, it has been proposed that the energy could come from slowly-varying flows by the self-oscillatory mechanism (?), or the Alfvénic vortex shedding (?), or random motions around footpoints of the oscillating loop (?). Apparently decayless patterns could also appear because of the development of the Kelvin–Helmholtz instability (e.g., ??).

The recent commissioning of the High Resolution Imager (HRI) of the Extreme Ultraviolet Imager (EUI, ?) onboard Solar Orbiter (?), opens up interesting perspectives in the high-resolution study of the decayless kink oscillation phenomenon. This extends beyond the resolution of the Atmospheric Imaging Assembly (AIA, ?) on the Solar Dynamics Observatory (SDO, ?), which is currently used for time–distance analysis of these oscillations. In particular, one may anticipate to resolve higher parallel harmonics which should result naturally from a broadband driver (e.g. ??), and obtain more robust information about the variability of instantaneous parameters of the oscillation (e.g. ?) and the oscillating loops (e.g. ??).

In this paper, we present the simultaneous detection of decay-
less kink oscillations with HRI and AIA, which has been success-
fully used for the observations of decayless kink oscillations for
almost ten years. The oscillation periods detected in this study vary
from 1-3 min, which is in the short limit of the previous detections
by AIA. We consider this study as the necessary step towards the
follow-up progression to shorter timescales detected by HRI, which
are not possible with AIA.

2 OBSERVATIONS AND DATA ANALYSIS

A series of 174 Å images was obtained with HRI from 22:58 UT
on 5 November 2021 to 00:28 UT on 6 November 2021. The field
of view (FOV) was 2048x2048 pixels with the pixel size of 0.492”
and the time cadence of 5 s. In this study, we use level 2 data.1 The
HRI telescope was pointed at near the disk centre, where a bundle
of loops with ongoing decayless kink oscillations was situated at an
active region. Simultaneous observation was acquired by SDO/AIA
at 171 Å with a pixel size of 0.6” and time cadence of 12 s. At the
time of observation, the Solar Orbiter was at a distance of 0.86 au
from the Sun, at the Stonyhurst heliographic longitude of -0.574°,
and the latitude of 1.987°; while SDO was at a distance of 0.99 au,
longitude of -0.0129°, latitude of 3.875°. In this case, see Fig.??,
both spacecraft have nearly parallel lines of sight (LoS). Also, such
a location determines the linear plate scale of HRI images as 306 km
pixel−1, while that of AIA images is 435 km pixel−1. With higher
spatial resolution and double temporal resolution, HRI allows us to
detect short-period low-amplitude kink oscillations of plasma struc-
tures, but our aim is to study the oscillation detected simultaneously
by both HRI and AIA. We select a similar 171 Å wavelength in AIA
in comparison with HRI 174 Å to confirm the oscillation detection.
In addition, magnetograms from the Helioseismic and Magnetic
Imager (HMI, ?), with resolution of 0.5” pixel−1 and cadence of
45 s, are used to establish the magnetic connectivity of the loops of
interest.

2.1 Alignment

After compensating the solar rotation in all data sets, it is found
that the pointing accuracy of HRI images as defined in the image
metadata (FITS keywords) is not sufficient for the present study: So
the HRI images need to be internally aligned to remove spacecraft
jitter.

One frequently used method to do image alignment is the cross-
correlation technique (?). This method first calculates the cross-
power spectrum of the reference image and aligned image, and
returns a cross correlation surface/matrix of the same size as
the image through the inverse Fourier transform. The distance
from the location of the maximum correlation to the surface cen-
tre in Cartesian axes is the offset in the x and y directions. Given
that the correlation matrix is in units of pixels, the location of the
maximum value is in a certain pixel. To achieve the sub-pixel
accuracy, we interpolate the correlation peak (?). The correspond-
ing SSWIDL function is tr_get_disp.pro, which is the core
block for the later developed routines align_cube_correl.pro and
fg_rigidalign.pro. The accuracy of fg_rigidalign.pro is several
tenths of a pixel, see https://hesperia.gsfc.nasa.gov/ssw/tr ace/idl/util/tr_r get_dis p.pro. Alternatively, upscaling the correlation surface can also result in sub-pixel
accuracy (e.g., ??).

Recently, ? developed an algorithm to locate the correlation
peak with high accuracy by treating the centroid of the correlation
surface as the peak. This algorithm first calculates the displacement
of the pixel-level and shifts the aligned image, then it performs
iteration of the offset calculation and shifting until the displacement
is less than one pixel, finally locates the centroid with accuracy
as high as 0.01 pixel (i.e., 36 km in the analysed data, i.e., 1/5 of
average amplitude of decayless oscillations 170 km) and shifts the
sub-pixel displacement (?). Considering its high accuracy, we apply
this method to align the HRI data in this study.

2.2 Co-alignment and motion magnification

After the internal alignment, co-alignment between HRI images and
AIA images closest in time is performed based on the common fea-
tures in both data sets. HMI data is aligned with AIA already. For
further analysis, sub-frames are extracted at the same FOV (indi-
cated by the red box in Fig.??(b)) and stacked into a 3D datacube,
respectively.

At 22:58 UT on 5 November 2021, the HRI telescope captures
a scene near the disk centre, including active region AR 12983 with
several bundles of loops evolving. During this 1.5-hour observation,
decayless kink oscillations of an ensemble of loops are observed,
and no flares or CMEs are reported in this region. A similar scene
is simultaneously recorded by AIA. As the characteristic displacement
amplitude (0.17 Mm) of decayless kink oscillations is less than
the pixel size of both datasets, we use the motion magnification
technique to magnify the transverse motions in the plane of the
sky (?). In this work, the magnification factor is 3, and smoothing
width is 4 minutes, which is longer than the oscillation periods of
interest. Having applied the motion magnification to HRI and AIA
datasets, we make time–distance (TD) plots (Fig.??) using slits (see
white slits in Fig. ??) directed across the oscillating loops, to reveal
the oscillatory patterns (see ?, for the methodological details).

3 RESULTS

3.1 Oscillation detection

Fig. ?? shows the full-disk AIA 171 Å image (panel (a)) and HRI
174 Å image (panel (b)) obtained at the beginning of the obser-
vation. The FOV of HRI is indicated by the blue box, and the
red rectangles indicate the FOV of panels (c)-(e), which is the re-
gion of interest where the oscillations occur. The bottom panels of
Fig. ?? display the HMI magnetogram (c), AIA 171 Å image (d), and
HRI 174 Å image (e), all of which are aligned. The sunspot is
situated at the bottom-left corner of FOV. The oscillations occur
in the bright loops near [-50°, 320°], connecting two small magnetic
patches of opposite polarities. The apparent distance between the
loop footpoints is 32 Mm, hence the loop length is estimated as
L = π × 32/2 = 51±16 Mm, assuming that the loop shape is semi-
circular. See also the online animation which shows the co-aligned
HRI 174 Å images (left) and AIA 171 Å images (right) with time
corrected.

The bundle of loops which hosts oscillations is shown in Fig. ??.
The images of upper and bottom rows are made with HRI and
AIA respectively. Besides the obvious difference in image qual-
ity and despite the slightly different bandpasses, the images appear

1 The EUI L2 data we used can be accessed via “EUI Data Release 5.0
2022-04”, see https://doi.org/10.24414/2qfw-tr95.
very similar. Within this bundle of loops, several distinguishable threads (denoted by the coloured arrows) evolve quickly, resulting in that the observed kink oscillations appear to be short-lived. Two slits “S1” and “S2” across the loops are used to make TD plots to reveal the oscillatory patterns. As shown in Fig. ??, all oscillations last for only several cycles, up to 15 minutes. The disappearance of oscillations is caused by changing of observational conditions, e.g., other loops come into the LoS, rather than damping. The oscillation signal of a certain thread is highlighted by curves of the same colour. These curves, marking the location of the loop centre or boundary at each instant of time, are determined by fitting the transverse loop profile for each instance of time with a Gaussian profile by gaussfit.pro.

To estimate the oscillation parameters, each oscillating signal is best fitted by a harmonic function with a linear background trend:

\[
A(t) = A_0 \sin \left( \frac{2\pi t}{P} + \phi \right) + c_0 + c_1 t.
\]

where \(A_0\) is the displacement amplitude, \(P\) is the oscillation period, \(\phi\) is the phase, and \(c_0\) and \(c_1\) are constants. The fitting results are summarised in Table ???. The details of best fitting curves are given in Appendix ???. Note that here the oscillation amplitude is linearly magnified by factor 3, so the original amplitude is \(A = A_0/3\). For convenience, the oscillating threads are numbered in the chronological order, i.e., from Thread 1 (T1 for short) to T7, corresponds to the green, cyan, red, yellow, white, blue, pink threads. The oscillation periods of T1 to T7 are within 1-3 minutes, ranging from 67 to 133 s. Compared with the previous observed events (e.g., ??), the oscillation periods in this study are rather short (see Section ??). In addition, displacement amplitudes vary from 27 km to 83 km, which is much lower than the average amplitude of 170 km (?). Note that the values of the parameters obtained in HRI and AIA are consistent, within error bars. The averaged periods from T1 to T7 are 84 ± 21 s, 74 ± 9 s, 104 ± 11 s, 83 ± 16 s, 87 ± 9 s, 111 ± 33 s, and 108 ± 6 s, respectively. The averaged amplitudes from T1 to T7 are 34 ± 14 km, 41 ± 13 km, 71 ± 14 km, 59 ± 18 km, 35 ± 9 km, 63 ± 16 km, 41 ± 14 km.

### Table 1. Oscillation parameters of different oscillating thread estimated in HRI and AIA data. Information includes the thread ID, data source, period (\(P\) in seconds), displacement amplitude (\(A\) in km, the magnified amplitude divided by magnification factor, i.e., \(A = A_0/3\)), and cross-correlation coefficient (\(C\)) of signals from these two data sets.

| Thread | Data  | \(P\) [s]  | \(A\) [km] | C     |
|--------|-------|------------|------------|-------|
| T1     | HRI 174 | 76 ± 11    | 24 ± 7     | 0.94  |
|        | AIA 171 | 91 ± 30    | 45 ± 22    |       |
| T2     | HRI 174 | 67 ± 8     | 28 ± 5     | 0.97  |
|        | AIA 171 | 80 ± 10    | 53 ± 22    |       |
| T3     | HRI 174 | 107 ± 8    | 70 ± 9     | 0.92  |
|        | AIA 171 | 100 ± 13   | 72 ± 19    |       |
| T4     | HRI 174 | 80 ± 8     | 47 ± 6     | 0.96  |
|        | AIA 171 | 86 ± 24    | 71 ± 30    |       |
| T5     | HRI 174 | 83 ± 9     | 28 ± 5     | 0.82  |
|        | AIA 171 | 90 ± 8     | 42 ± 13    |       |
| T6     | HRI 174 | 104 ± 5    | 31 ± 10    | 0.95  |
|        | AIA 171 | 112 ± 6    | 51 ± 17    |       |
| T7     | HRI 174 | 89 ± 10    | 44 ± 5     | 0.97  |
|        | AIA 171 | 133 ± 55   | 83 ± 26    |       |

3.2 Correlation of oscillations in two data

Signals from HRI (see Fig. ??(a1)-(a2)) and AIA (see Fig. ??(b1)-(b2)) are very similar in shape but AIA signals are delayed by around 1 minute. During the observation, the distance difference of two spacecrafts from the Sun was 1.98 × 10^7 km, giving the light travel time of 66 s. That is to say, the EUV received light 66 s earlier than AIA. Taken this into account, we correct the AIA signals by shifting the signal forward by 66 s. As shown in Fig. ??, the corrected AIA and HRI signals are consistent with each other, both in space and time. To quantify the correlation of the oscillations in two data, the cross-correlation coefficient between the HRI and corrected AIA signal is calculated for each thread and displayed in Table ???. The cross-correlations coefficient between signals from two data sets for T1 to T7 is 0.94, 0.97, 0.92, 0.96, 0.82, 0.95, 0.97, respectively. This indicates that oscillations seen with the two instruments correlate well with each other.

3.3 Short periodicity

Fig. ??(a) shows the scaling of the loop length and oscillation periods obtained in this study and previous reports of decayless kink oscillations of coronal loops (e.g., ?????????). As mentioned in Section ??, the oscillation periods in our work are rather short (< 3 min), so our data points lie in the lower left corner of the scaling plot. The previously established linear scaling of the loop length and period is not broken down by our results, as demonstrated by the black line, the best linear fit with the gradient of about 1.0 s Mm^-1.

In our observations, only certain segments near the loop top are clearly seen, see Fig. ???. Thus we cannot identify the exact locations...
of the footpoints of oscillating threads, and take two polarities connected by this set of loops as approximate footpoints in the length estimation. The shaded box in Fig. ??(a) indicates the uncertainty in the loop length. We need to note that the period depends also on the local kink speed, which should explain the data scattering. During the observation, the oscillating loops are evolving, hence the instantaneous local kink speed is changing too. Also, a histogram of periods overplotted with the cumulative probability is shown in Fig. ??(b).

4 DISCUSSION

Using HRI and AIA imaging data, we analyse decayless kink oscillations of several loops anchored at a quiescent active region. In similar observational channels (171 Å of AIA and 174 Å of HRI), and with almost parallel LoS, the dynamics of loops are found to be visually identical in these two data sets.

The observed oscillation signals are short-lasting, with amplitude below 0.1 Mm and periods shorter than 2 min. The AIA signals delay for 66 s compared to HRI because of different distances from the Sun. After the time correction, cross-correlation coefficients between oscillation signals in two data sets are typically higher than 0.9, suggesting oscillations recorded by two instruments are well consistent spatially and temporally. Therefore, the observed oscillations are of the physical nature.

4.1 Detection of short time scales

The period of analysed oscillations varies from 67 s to 133 s, which is rather short in comparison to previously reported cases. The uncertainties in the period estimation in Table ?? are connected with a relatively short duration of the oscillation detection (for some
Figure 3. The dynamics of analysed threads. Slits “S1” and “S2” are used to make time–distance (TD) maps in Fig. ???. The coloured arrows denote the oscillating threads which have distinct oscillatory patterns. The images are enhanced to reveal the threads, by applying a high-boost mask.

Figure 4. TD maps which display decayless kink oscillations. The dashed lines denote the observation time of HRI images in Fig. ???. The coloured curves indicate the displacement location of centre/edge of corresponding oscillating threads in Fig. ???. The magnification factor is 3 for both data sets.
signals we only have a dozen of the loop displacement measurements), choice of the model to fit (the observed oscillatory signals may not be well described by a sine function), and the effects of slowly-varying background, surrounding threads, and noise.

In Fig. 7(b), the number of cases with periods longer than 6 min or shorter than 3 min is 39, which is smaller than a third of the total number of 116 cases. On one hand, long periodicities (> 6 min) are possibly underreported because the long loops (> 400 Mm) are rare and short-lived. Moreover, the detection of oscillations requires the preferable observational conditions, e.g., the contrasted boundary of the oscillating loop, to exist for longer than three oscillation periods, which is less possible for longer periods. On the other hand, short periodicities are rarely detected due to (1) the limited resolution (both temporal and spatial) of available instruments; (2) shorter loops are usually not well isolated and they evolve rapidly.

Since the period of kink oscillations scale linearly with the loop length (assuming for a certain parallel harmonics), short periodicity can be formed in the shorter loop, that is, loop with lower height. Shorter plasma structures usually occur at the small-scale active regions (e.g., newly emerging ones) or short-distance magnetic polarity-pairs. Therefore, short-period decayless kink oscillation possesses the potential for seismological diagnostics of the confined plasma at some certain coronal environments. Recently, reported decayless kink oscillations of loops (averaged loop length is 23 Mm) in mini-active regions, and successfully applied these oscillations to estimate Alfvén speed, magnetic field strength of the hosting loops. In addition, short periodicities are of interest for the study of higher parallel harmonics of kink oscillations, and nonlinear cascade, e.g., the Kelvin-Helmholtz instability (e.g., ??).

The two-spacecraft detection of short periodicity in our work moves a step closer to unexplored regime of shorter oscillation periods, e.g., shorter than 1 minute. It shows that our current methods are applicable for short-period oscillations taken with EUI data. In particular, a candidate event of short-period decayless oscillations taken by EUI was observed by T, with oscillation periods of 14 s and 30 s in two short loops of 4.5 Mm and 11 Mm respectively. Moreover, in addition to the discussed kink oscillations, HRI with time cadence up to 2 s could resolve such short period wave phenomena as sausage oscillations of flare loops with period of tens of seconds (e.g., ?, and references therein).

4.2 The problem of alignment

HRI images are affected by the spacecraft jitter. Some of this jitter (but not all) is measured by the spacecraft itself and recorded in the metadata of the EUI images (FITS World Coordinate System keywords). For the EUI Full Sun Imager (FSI), these pointing information is further updated on the ground with a limb fitting procedure. For the partial FOV images taken by HRI this is however not possible and only the spacecraft provided pointing information is available. Therefore additional alignments internal to the analysed data cube are needed to get rid of the remaining spacecraft jitter. For the detection of oscillations of low amplitude and short period, the accuracy of the alignment is crucial as inaccurate alignment may lead to the appearance of artificial oscillations.

As mentioned in Section 7?, the correlation-based internal alignment could achieve sub-pixel accuracy. In practice, other factors affecting the accuracy include the selection of the correlated region (location and size), and the frames correlated at one time etc. In addition, it is found that the image enhancement prior to the alignment helps to improve accuracy (e.g., ??). In the final step of alignment, 2D shifting with non-integer displacement by interpolation would degrade the spatial resolution of images. However, the loss of information is very minor. The high correlation of small-amplitude kink oscillations detected with HRI and AIA indicates that this internal alignment procedure is highly robust.

5 CONCLUSIONS

In this study, short-period decayless kink oscillations of an ensemble of loops are investigated, utilizing EUI-HRI 174 Å image sequence and co-aligned AIA observation in the 171 Å channel. The analysis of imaging data is performed with the motion magnification technique. The observed oscillating loops have average length of 51 Mm, oscillation periods are about 60-100 s, and displacement amplitudes of 27–83 km. Given that EU and AIA have different distances from the Sun, oscillations captured by AIA are delayed by 66 s. After compensation of this time lag, oscillations obtained in two data are correlated well with each other, with their cross correlation coefficients ranging from 0.82 to 0.97. It is confirmed
that EUI-HRI sees the same oscillations as AIA, a well-tested instrument, which is a starting point for progressing to the study of shorter oscillation periods with HRI.

ACKNOWLEDGEMENTS

Solar Orbiter is a mission of internal cooperation between ESA and NASA, operated by ESA. The EUI instrument was built by CSL, LAS, MPS, MSSS/UCL, PMOD/WRC, ROB, LCF/IO with funding from the Belgian Federal Science Policy Office (BELSPO/PRODEX PEA C4000134088); the Centre National d’Études Spatiales (CNES); the UK Space Agency (UKSA); the Bundesministerium für Wirtschaft und Energie (BMWi) through the Deutsches Zentrum für Luft- und Raumfahrt (DLR); and the Swiss Space Office (SSO). DATA AVAILABILITY

In this paper, we analysed data using the Interactive Data Language (IDL), SolarSoftWare (SSW) package, and the motion magnification technique (?), and the Solar Bayesian Analysis Toolkit (SoBAT, ?). The EUI data are available at DOI: https://doi.org/10.24414/2qfw-tr95. The AIA and HMI data are available at http://jsoc.stanford.edu/. The data are processed and analysed using the routines available at https://www.lmsal.com/sdodocs/doc/dcur/SDOD0060.zip/zip/entry/ (Section 7). The motion magnification code is available at https://github.com/Sergey-Anfinogentov/motion_magnification.

APPENDIX A: CURVE FITTING

Here we demonstrate the best sinusoidal fits of the oscillation signals of T1–T7 obtained in the HRI and AIA data. The signals (see the red dots in Fig. ??) are best fitted with Eq. ?? to estimate the oscillation period and displacement amplitude, using the Markov Chain Monte Carlo method (?; the algorithm is available at https://github.com/Sergey-Anfinogentov/SoBAT). The best fitting parameters are shown in Table ?? and the best fitting curves are represented by the solid curves in Fig. ??.
