ABSTRACT

We report the most rapid rate of period change measured to date for a pulsating DA (hydrogen atmosphere) white dwarf (WD), observed in the 292.9 s mode of WD 0111+0018. The observed period change, faster than \(10^{-12} \text{ s}^{-1}\), exceeds by more than two orders of magnitude the expected rate from cooling alone for this class of slow and simply evolving pulsating WDs. This result indicates the presence of an additional timescale for period evolution in these pulsating objects. We also measure the rates of period change of nonlinear combination frequencies and show that they share the evolutionary characteristics of their parent modes, confirming that these combination frequencies are not independent modes but rather artifacts of some nonlinear distortion in the outer layers of the star.

Key words: stars: individual (WD0111+0018) – stars: oscillations (including pulsations) – stars: variables: general – white dwarfs

Online-only material: color figures

1. INTRODUCTION

White dwarf (WD) stars represent the final evolutionary stage of all single low-mass stars, and are thus representative of the future of the majority of stars in our Galaxy. They are primarily composed of the inert by-products of hydrogen and helium fusion, and their evolution is dictated by the rate at which these carbon and oxygen ions lose their residual thermal energy (Mestel 1952). This cooling takes billions of years.

However, we can witness this cooling on human timescales by watching the WDs that pulsate. These variable stars come in several classes, based on their dominant atmospheric composition (their strong surface gravity and rapid gravitational settling leads to chemically homogenous photospheres). Here we will restrict our discussion to the coolest class of such pulsators: the hydrogen-atmosphere DAV (or ZZ Ceti) stars, found in an instability strip between 10,800 and 12,300 K for standard log \(g = 8.0\) (Koester & Holberg 2001; Bergeron et al. 2004; Mukadam et al. 2004, 2006; Gianninas et al. 2005, 2006).

Aside from their variability, which is brought on by a hydrogen partial-ionization zone in the star’s non-degenerate atmosphere, DAVs appear to be normal WDs. They are therefore believed to be representative of evolution for all DA WDs (Robinson 1979; Fontaine et al. 1985; Bergeron et al. 2004). Cooling from neutrino emission is expected to be negligible for DA WDs within the ZZ Ceti instability strip (Winget et al. 2004), and their evolution should be dominated by radiative surface emission.

The C/O-core DAVs undergo multi-periodic, non-radial \(g\)-mode pulsations with periods between roughly 100 and 1400 s. Seismology using these \(g\)-mode pulsations has enabled us to constrain the mass, core and envelope composition, rotation rate, and the behavior of convection in these objects (see reviews by Winget & Kepler 2008; Fontaine & Brassard 2008; Althaus et al. 2010). These modes are often stable in period and amplitude, especially for the hot DAVs (hDAVs) near the blue-edge of the ZZ Ceti instability strip. hDAVs are expected to show an extremely slow period drift caused by the gradual cooling of the star.

Two of the longest-studied hDAVs are G117-B15A and ZZ Ceti itself (also referred to as R548), which have been observed since the early 1970s. Both show considerable stability in their largest-amplitude modes. The rate of change of period with time, \(dP/dt\), of the dominant 215.2 s mode in G117-B15A has been measured to be \((4.19 \pm 0.73) \times 10^{-15} \text{ s}^{-1}\) (Kepler et al. 2012). R548 has been observed since 1970, but more sparingly. For the 213.1 s periodicity in R548, Mukadam et al. (2012) determine \(dP/dt = (3.3 \pm 1.1) \times 10^{-15} \text{ s}^{-1}\). These values have taken decades of observations, and are in line with theoretical predictions of rates of period change from cooling alone in DAVs of \(dP/dt < 10^{-14} \text{ s}^{-1}\) (Bradley et al. 1992; Bischoff-Kim et al. 2008; Córresco et al. 2012).

After more than nine years of monitoring, we have found evidence for an hDAV that has a rate of period change inconsistent with cooling alone. The period change in the highest-amplitude periodicity for that star, SDSS J011100.63+001807.2 (hereafter WD 0111+0018; \(g = 18.7 \text{ mag}\), exceeds \(10^{-12} \text{ s}^{-1}\). This observed rate of change of period with time is several orders of magnitude faster than predicted from cooling alone for this 11810 K WD. It therefore signifies some physical process operating on a considerably shorter timescale.

In this paper, we present our observations of period evolution in the four highest-amplitude periodicities present in WD 0111+0018. In Sections 2 and 3 we outline our observations and analysis, and we reserve Sections 4 and 5 for a discussion of possible explanations for this rapid period change and our conclusions.

2. TIME-SERIES PHOTOMETRIC OBSERVATIONS

Mukadam et al. (2004) discovered pulsations in WD 0111+0018, resulting from a search for variable DAs. The WD was initially targeted as a result of model atmosphere fits to spectra from the Sloan Digital Sky Survey: with \(T_{\text{eff}} = 11510 \pm 110 \text{ K}\).
and log $g = 8.26 \pm 0.06$, the object was predicted and confirmed to be a DAV within the ZZ Ceti instability strip.

Using new treatments of line broadening theory, Tremblay et al. (2011) refined the temperature and surface gravity of WD 0111+0018 to $T_{\text{eff}} = 11,810 \pm 190$ K and log $g = 8.17 \pm 0.07$, which corresponds to a mass of $M_{\text{WD}} = 0.71 \pm 0.04 M_\odot$ and a cooling age of 510 Myr.

Including the initial discovery observations in early 2003, the White Dwarf Group at the University of Texas at Austin has logged a total of more than 136 hr of observations of WD 0111+0018 on 39 separate nights. As the journal of observations has logged a total of more than 136 hr of observations of WD 0111+0018.

### Table 1

| Subgroup | UT Date     | Length (hr) | Seeing (") | Exp. (s) |
|-----------|-------------|-------------|------------|----------|
| 2003a     | 2003 Jan 27 | 1.5         | 2.3        | 15       |

and the periodograms of this 5.5 hr run illustrates that the four periodicities of interest, seen marked, can be resolved in a single night. (A color version of this figure is available in the online journal.)

The raw science frames are calibrated by dark subtraction and flat fielding. We perform weighted, circular, aperture photometry on the calibrated frames using the external IRAF package ccdproc written by Antonio Kanaan (the reduction method is outlined in Kanaan et al. 2002 and Mullally et al. 2005). We divided the sky-subtracted light curves using two bright comparison stars in the field, SDSS J011055.57+001850.6 ($g = 15.0$ mag) and SDSS J011056.17+001955.8 ($g = 16.2$ mag), to correct for transparency variations. Using the WQED software suite (Thompson & Mullally 2009), we fit and subtract out a low-order polynomial (at the timescale of several hours) to each run to remove any long-term trend caused by atmospheric extinction, and apply a timing correction to each observation to account for the motion of the Earth around the barycenter of the solar system (Stumpff 1980).

### 3. LIGHT CURVE ANALYSIS

#### 3.1. The Pulsation Spectrum of WD 0111+0018

The light curve of WD 0111+0018 features modulation at four distinct periodicities between 100–300 s, which can be well resolved in a 3 hr run in good conditions (see Figure 1). In order to most accurately identify these four periods, we begin by computing a Fourier transform of our entire data set. Using these results as an initial guess, we then perform a nonlinear least-squares fit for the frequency, amplitude, and phase of the four periodicities present.

This allows us to isolate an initial estimate of the periods of the four highest-amplitude pulsations present in WD 0111+0018, which we use to construct an initial $(O - C)$ diagram. The amplitudes for these four periodicities never fall below 0.5%;...
the amplitudes listed in Table 2 are weighted-mean amplitudes using each subgroup.

We perform this analysis independently for all 18 subgroups of our data. The subgroups are created by combining data from as many contiguous nights as possible; no combined subgroup spans more than two weeks. These subgroups have been identified in Table 1. In each case, the periods we determine for each subgroup match the periods we have found for the entire data set, within the uncertainties.

We fix these periods and compute a simultaneous linear least-squares fit for each subgroup to create an \((O-C)\) diagram. Thus, the uncertainties in our \((O-C)\) diagrams represent formal uncertainties on the least-squares fit for the phase on at least 1—and as many as 3—nights of data, separated by as many as 10 days.

We will refer to the two highest-amplitude periodicities as the parent modes \(f_1\) and \(f_2\), and the two smaller-amplitude periodicities \(2f_1\) and \(f_1 + f_2\) as the combination frequencies, such that the frequency for \(2f_1\) is (within the uncertainty) exactly twice the frequency of \(f_1\) and the frequency for \(f_1 + f_2\) is the sum of the frequencies of \(f_1\) and \(f_2\). We will discuss in more detail these combination frequencies and how they arise in Section 4.1.

Additionally, we note the presence of an additional combination frequency \(2f_2\) at 127.8 s, visible but not labeled in Figure 1. In fact, we detect at least five additional nonlinear combination frequencies. Using all of our light curves from 2009 to early 2012 to detect as many combination frequencies as possible, we find \(f_1 = 2.739(29)\%\), \(f_2 = 1.526(31)\%\), \(f_1 + f_2 = 0.472(27)\%\), \(2f_1 = 0.732(28)\%\), \(2f_2 = 0.193(25)\%\), \(3f_1 = 0.143(44)\%\), \(2f_1 + f_2 = 0.295(98)\%\), \(f_1 + 2f_2 = 0.147(44)\%\), \(3f_2 = 0.068(28)\%\). However, the amplitudes of most of the combination frequencies are too low to produce an \((O-C)\) diagram for all subgroups, so we do not include them in the \((O-C)\) analysis.

3.2. Constructing an \((O-C)\) Diagram

We demonstrate a secular change in the pulsation periods of WD 0111+0018 by constructing \((O-C)\) diagrams, where we compare the observed time of maximum for a pulsation \((O)\) to when we expect such a maximum assuming that the pulsation obeys a constant period \((C)\).

Following Kepler et al. (1991), if the pulsation period is changing slowly with time, we can expand the observed time of maximum of the \(E\)th pulse, \(t_{E}\), in a Taylor series around \(E_0\): 

\[
t_{\text{max}}|_{E} = t_{\text{max}}|_{E_0} + \frac{dt_{\text{max}}}{dE}|_{E_0}(E - E_0) + \frac{1}{2}\frac{d^2t_{\text{max}}}{dE^2}|_{E_0}(E - E_0)^2 + \ldots, \tag{1}
\]

where the epoch is \(E = t/P\) and the change in arrival time with epoch, \(dt/dE\), is the period, \(P\). If we drop all terms higher than second order (assuming that \(P\) is negligible), we arrive at the classic \((O-C)\) equation

\[
O - C = \Delta t_0 + \Delta P_0 E + \frac{1}{2} P_0 \dot{P} E^2 + \frac{1}{6} (\ddot{P} P_0^2 + \dot{P}^2 P_0) E^3, \tag{2}
\]

where \(t_0\) is the time of first maximum, \(\Delta t_0\) is the uncertainty in this time, \(P_0\) is the pulsation period at this time of first maximum, and \(\Delta P_0\) is the error in the observed period. Thus, any secular change in the period, \(dp/dt\), will cause a parabolic curvature in an \((O-C)\) diagram.

We construct an initial \((O-C)\) diagram using the periods identified in Section 3.1. We then iteratively adjust \(t_0\) and \(P_0\) by the zeroth- and first-order terms from our best second-order fit until the adjustments are smaller than the uncertainty in these terms; these uncertainties result from the covariance matrix. Our recomputed final \((O-C)\) diagrams use these final ephemeris and periods, which can be found for each mode in Table 2. The final \((O-C)\) diagrams are shown in Figure 2. Table 3 presents the times of maximum from each subset of our observations.

3.3. Observed Rates of Period Change

Mullally et al. (2008) published an \((O-C)\) diagram of \(f_1\) in WD 0111+0018, noting the large curvature but urging caution given the sparse coverage. Still, a rather high rate of change of period with time was observed: \((3.87 \pm 0.43) \times 10^{-12}\) s s\(^{-1}\).

We have added another 86 hr of observations, more than doubling the coverage, and confirm this large trend in the \((O-C)\) diagram of \(f_1\). We have additionally been able to make \((O-C)\) diagrams for three other periodicities. These diagrams can be found in Figure 2.

Using Equation (2), a best-fit parabola to each \((O-C)\) diagram yields a rate of change of period with time. We list these results in Table 2. Our results for \(f_1\) actually fall within the errors of the Mullally et al. (2008) result, at \((4.280 \pm 0.042) \times 10^{-12}\) s s\(^{-1}\) (or \(0.135 \pm 0.001\) ms yr\(^{-1}\)). We also strongly establish the need for a second-order fit rather than a first-order fit to the 18 data points: The best second-order fit for the \((O-C)\) diagram of \(f_1\) has \(\chi^2 = 145\) (15 degrees of freedom or d.o.f.), whereas the best linear fit has \(\chi^2 = 10292\) (16 d.o.f.).

Although the \((O-C)\) diagrams for WD 0111+0018 appear parabolic, as we would expect if the pulsations periods were changing secularly, we also would like to establish the timescale of variability if these observed trends are instead periodic in nature, since a portion of a sinusoid can mimic a parabola. For \(f_1\) we find that the data can be well fit by a sinusoid with a 101-year period and a 3931 s \((O-C)\) amplitude, with a \(\chi^2 = 142\) (15 d.o.f.). However, we will only continue our analysis in the framework of a secular period change.

In the future, a third-order fit including the acceleration in the period change may be needed to best represent the data. This would enter the \((O-C)\) equation as

\[
O - C = \Delta t_0 + \Delta P_0 E + \frac{1}{2} P_0 \dot{P} E^2 + \frac{1}{6} (\ddot{P} P_0^2 + \dot{P}^2 P_0) E^3.
\]

Currently, a third-order polynomial fit to the \((O-C)\) diagram of \(f_1\) has \(\chi^2 = 143\) (14 d.o.f.), which reduces to a value still slightly higher than that for a second-order fit. The best third-order fit would correspond to

\[
\dot{P} = (-2.3 \pm 1.4) \times 10^{-21}\text{ s s}^{-2},
\]

with a second-order term corresponding to \(dp/dt = (4.65 \pm 0.23) \times 10^{-12}\text{ s s}^{-1}\).

We have also attempted a direct measurement of \(dp/dt\) by computing a nonlinear least-squares fit to find the period for each subgroup. A best-fit line to these periods over time yields a rate
of change of period with time. Unfortunately, there is simply not enough data for this direct measurement. The best result comes for $f_1$, where we determine $dP/dt = (5.5 \pm 6.8) \times 10^{-12} \text{ s}^{-1}$, consistent with the $(O - C)$ value but not yet significant.

The other independent parent mode in WD 0111+0018, $f_2$, shows a much slower period change than $f_1$. Still, it is significantly faster than predicted by cooling theory, with a best-fit parabola that corresponds to $(3.40 \pm 0.58) \times 10^{-13} \text{ s}^{-1}$ (or $0.011 \pm 0.002 \text{ ms yr}^{-1}$). In this case, a second-order fit is only marginally better than a linear fit: The best-fit parabola has $\chi^2 = 93.8 \text{ (15 d.o.f.)}$, whereas the best-fit straight line has $\chi^2 = 128.7 \text{ (16 d.o.f.)}$.

Noise can cause scatter about a straight line in an $(O - C)$ diagram, especially over a relatively short baseline (e.g., Kepler et al. 1991). Since a bad period can cause a dominant linear term, we caution that the rate of change of the $f_2$ periodicity may still be somewhat slower than the value cited in Table 2 if the period we use for our $(O - C)$ diagrams is off by as little as 0.06 ms. Therefore, we recommend that our value be construed as an upper limit on the rate of change of period with time of $f_2$. As with the other parent mode, we also investigated the best possible periodic rather than secular fit, and found a sinusoid with a 9540-year period and $3051490 \text{ s}$ $(O - C)$ amplitude, with a $\chi^2 = 93.8 \text{ (15 d.o.f.)}$. If such a trend were from an external companion, it would require a $10.8 M_\odot$ unseen companion at 401 AU.

A Monte Carlo simulation of the uncertainties using the software package Period04 (Lenz & Breger 2005) indicates that our formal least-squares uncertainties on the phases used to construct the $(O - C)$ diagrams are underestimated by at most 10%. Thus, the scatter about our residuals (evident by the large $\chi^2_{\text{red}}$ quoted above for the second-order fits, e.g., $\chi^2_{\text{red}} = 9.7$ for $f_1$) may not be entirely the result of underestimated uncertainties. The deviation about the residuals is consistent with the observed scatter in other long-studied DAVs, such as G117-B15A (see Figure 2 of Kepler et al. 2005).

We have investigated the stability of the four highest-amplitude periodicities in WD 0111+0018 by plotting the amplitudes of each determined by a linear least-squares fit to each subgroup using the periods in Table 2. This result is shown in Figure 3. It is meaningful since all observations were obtained and reduced in an identical manner. We have also marked the weighted-mean amplitude for each mode with dotted lines.

There are considerable deviations about this mean compared to the formal uncertainties, such that only the periodicity at $f_1$ has a constant amplitude in a statistically meaningful way. While the amplitudes of the $f_1$ and $f_2$ modes do not appear constant over our entire data set, the deviations from the mean do not appear coherent, and cannot explain the large-scale parabolic changes we observe in observed times of maxima.

Finally, in line with the original intentions of this data set, we have investigated whether periodic changes in the times of maxima can explain the scatter observed about the residuals after subtracting the dominant parabolic terms. This scatter might reveal the presence of an unseen companion. However, a Fourier transform of all four $(O - C)$ residuals, after subtracting the dominant parabolic terms identified in Figure 2, show no peaks above twice the mean noise level of 1.5 s. We can thus conservatively rule out the presence of any companion more massive than Jupiter at a current orbit between 2 and 10 AU; the scatter is predominantly incoherent and cannot currently be attributed to an unseen companion.

4. DISCUSSION

4.1. Nonlinear Combination Frequencies

Before focusing on the rapid rates of period change, we first draw attention to the observation that $dP/dt$ for the $2f_1$ and

![Figure 2](https://example.com/figure2.png)

**Figure 2.** $(O - C)$ diagrams for the four highest-amplitude periodicities present in WD 0111+0018. The $f_1$ and $2f_1$ $(O - C)$ diagrams are nearly identical, which strongly suggests that nonlinear combination frequencies in DAVs are not independent pulsation modes but are directly tied to their parent modes. A best-fit parabola yields a rate of change of period with time: See Table 2 for full solutions. (A color version of this figure is available in the online journal.)
### Table 3

| Time of Maximum (BJD$_{TDB}$) | Epoch | $(O - C)$ | $\sigma$ |
|------------------------------|-------|-----------|----------|
| $f_1$                        | 2452668.431022 | 551 | $-0.11$ | 4.41 |

**Figure 3.** Amplitude evolution of WD 0111+0018 over nine years of observations. The dotted lines represent the weighted-mean amplitude over the entire data set, shown in Table 2. While our data show that the amplitudes are not stable over the entire data set, they rule out a large-scale amplitude increase as the cause of the large trends in the $(O - C)$ diagrams shown in Figure 2. (A color version of this figure is available in the online journal.)

$f_1 + f_2$ combination frequencies evolve exactly in lockstep with their parent modes. For example, we expect the $2f_1$ combination frequency to have half the rate of change of period with time of its parent mode, since $2f_1$ has half the period. We expect $(2.140 \pm 0.042) \times 10^{-12}$ s$^{-1}$, and in fact observe $(2.075 \pm 0.044) \times 10^{-12}$ s$^{-1}$, in excellent agreement.

The $f_1 + f_2$ combination frequency is a bit more complicated, given that it is a sum of the parent frequencies and not an integer ratio. We expect its rate of change of period with time to be

$$\frac{dP_3}{dt} = \frac{P_2^2}{P_1} \frac{dP_1}{dt} + \frac{P_1^2}{P_2} \frac{dP_2}{dt},$$  

(3)

where $P_1 = f_1^{-1}$, $P_2 = f_2^{-1}$, and $P_3 = (f_1 + f_2)^{-1}$. We thus expect a rate of $(1.027 \pm 0.009) \times 10^{-12}$ s$^{-1}$ and in fact observe $(1.109 \pm 0.030) \times 10^{-12}$ s$^{-1}$. As with $2f_1$, our observed rates match the predictions exactly within the errors.

This lends convincing evidence that these nonlinear combination frequencies are not independent modes themselves, but rather artifacts of some nonlinear distortion in the outer layers of the star. They are thus directly tied to the parent modes, and evolve at exactly the same rate as these parent modes. This is an
important result that convincingly demonstrates the nonlinear nature of these signals.

In fact, an extensive theory explaining the creation of nonlinear combination frequencies in DAVs was introduced by Brickhill (1992). He attributed the nonlinearities to the changing thickness of the star’s convection zone, which acts to distort a linear input signal. Physically, local surface temperature variations lead to changes in the depth of the convection zone, which both absorb and release energy. Because this process is so sensitive to temperature ($\propto T^{-96}$ for a DAV; Montgomery 2005), these variations in the depth of the convection zone lead to nonlinear effects in the observed light curve. An alternate explanation that may play a role for the hottest DAVs is given by Brassard et al. (1995) and Fontaine & Brassard (2008). They invoke the nonlinear response of the flux observed in a passband to the temperature (i.e., the “$T^4$” nonlinearity). Regardless of the source of these nonlinearities, our result confirms that the phase evolution of these combination frequencies mirrors that of their parent modes. These combination frequencies are thus directly tied to their parent modes.

The presence of nonlinear combination frequencies may also be useful in identifying the spherical degree ($\ell$) and azimuthal order ($m$) of the parent modes. In an investigation of eight DAVs, Yeates et al. (2005) found that the amplitudes of combination frequencies are too large to be created by the $T^4$ nonlinearity, and are probably due to the higher-order temperature dependence of the convection zone. They employed the formalism of Wu (2001), who derived an analytical expression for the amplitudes of the combination frequencies in the context of the Brickhill framework of a depth-varying convection zone. Using the ratio of the amplitudes of the parent and combination frequencies, Yeates et al. derived constraints on the $\ell$ and $m$ value of the parent mode.

With the same goal in mind, we have used our own code to automatically search for combinations of $\ell$ and $m$ that best fit the observed amplitudes in WD 0111+0018. This code uses a genetic algorithm to efficiently sample parameter space; see Section 4.1 of Provencal et al. (2012) for more details. We run this algorithm 1000 times so that we obtain 1000 estimates of the best-fit parameters.

The method of Wu (2001) is only applicable to second-order combinations, i.e., $2f_1$ or $f_1 + f_2$ but not $3f_1$. Even with just three independent combination amplitudes we are able to find constraints. Consistently, we best reproduce the observed amplitude ratios (we have used the amplitudes of the 2009–2012 group, provided in Section 3.1) when we allow the $f_1$ parent mode at 292.9 s to be an $\ell = 1$, $m = 0$ mode. We also find the $f_2$ parent mode at 255.7 s to be an $\ell = 2$, $m = \pm 1$ mode. Additionally, these fits find $\tau_0 = 137.8 \pm 11.8$ s, $N = -82.0 \pm 3.6$, and $\theta = 34.6^\circ \pm 2.5^\circ$.

We thus adopt an interpretation that $f_1$ is an $m = 0$ dipole ($\ell = 1$) mode and $f_2$ is a quadrupole ($\ell = 2$) mode. The constraints on the azimuthal order of $f_2$ are less conclusive. We will use this information to help constrain our asteroseismic models, which will in turn inform our attempts at understanding the observed $dP/dt$.

4.2. Expected Rates of Period Change

We can immediately rule out the possibility that an unseen external body is vigorously tugging WD 0111+0018 away from our line of sight, causing a light-travel time effect that is manifest as the increasing delay in pulse arrival times. Rapid space motion would affect all modes identically, and the periodic modulation in the mode $f_2$ is more than an order of magnitude slower than that of $f_1$, as we found in Section 3.3. We must be observing a phenomenon internal to the WD.

We expect cooling to be the dominant evolutionary effect of an isolated DAV, and this cooling timescale should have a direct effect on the period evolution of modes in a pulsating WD. To first order, as a WD cools it becomes more degenerate. This causes a decrease in the square of the Brunt–Väisälä frequency, $N^2$. The Brunt–Väisälä frequency is essentially the oscillatory frequency of an adiabatic fluid displacement in a convectively stable medium. In the limit of low temperature and complete degeneracy, where pressure does not depend on temperature, a displaced fluid element would remain in pressure and density equilibrium with its surroundings. It would stay put and thus have zero oscillatory motion—and thus a zero $N^2$. Thus, $N^2$ decreases with increasing degeneracy, and therefore decreasing temperature (see Kim 2007).

The period of a $g$-mode pulsation is inversely proportional to the Brunt–Väisälä frequency (Unno et al. 1989). Therefore,
cooling will cause a secular increase in a pulsation period with time, which can be estimated from the cooling timescale predicted from Mestel theory, as well as full evolutionary models. Predicted rates of period change for DAVs undergoing simple cooling are of the order of $10^{-15}$ s s$^{-1}$; we find observational evidence to support this timescale from observations of G117-B15A and R548 (Kepler et al. 2012; Mukadam et al. 2012). The 215.2 s mode in G117-B15A and the 213.1 s mode in R548 are most likely either an $\ell = 1$, $k = 1$ mode or an $\ell = 1$, $k = 2$ mode, depending on the adopted hydrogen layer mass (Bischoff-Kim et al. 2008; Romero et al. 2012).

We note that the work of monitoring long-term phase evolution of DAVs requires a mode coherent in amplitude and phase. This is usually not the case for the cooler DAVs, which evidence strong amplitude modulation and a corresponding lack of stability in phase (e.g., Kleinman et al. 1998; Dolez et al. 2006). One cool DAV has, for at least a brief time, shown enough phase coherence to create a meaningful $(O-C)$ diagram: The 615.2 s mode in G29-38 (Kleinman 1995), which showed a coherent but extremely rapid phase change, more than 200 s over less than three months of monitoring in 1988 (Winget et al. 1990).

There is also evidence that the 274.8 s mode in R548 has a $dP/dt > 10^{-13}$ s s$^{-1}$ (Mukadam et al. 2003), and that the 270.5 s and 304.1 modes in G117-B15A have $dP/dt > 3 \times 10^{-14}$ s s$^{-1}$ (Kepler et al. 2005). Still, most modes in DAVs observed to date simply do not show enough coherence to create stable $(O-C)$ diagrams.

WD stars with heavier cores should cool faster than those that are lighter. Indeed, spectral fits show that WD 0111+0018, at $\simeq 0.710M_\odot$, is slightly more massive than G117-B15A and R548, which are between 0.59 – 0.60 $M_\odot$. The effective temperature of G117-B15A and R548 are of the order of 10$^4$ K, 766:42 (9pp), 2013 March 20

The Astrophysical Journal, 766:42 (9pp), 2013 March 20

Figure 5. Propagation diagram for a representative asteroseismic fit, a WD model with stellar mass 0.710 $M_\odot$, an effective temperature $T_{\text{eff}} = 11,630$ K, an He envelope mass of $M_{\text{He}}/M_* = 10^{-2.1}$, and an H envelope mass of $M_{\text{H}}/M_* = 10^{-4.5}$. The run of the Brunt–Väisälä frequency is shown in blue. The run of the Lamb (acoustic) frequency for an $\ell = 1$ mode is shown as a dashed magenta line, while the Lamb frequency for an $\ell = 2$ mode is shown as a solid black line. The horizontal axis is in fractional mass units; the surface is to the right, while the center is to the far left. The base of the convection zone can be seen as the sharp drop in $N_2^2$ around $(1 - M_*/M_\odot) \simeq 10^{-14}$.

(A color version of this figure is available in the online journal.)

Solution 2, $f_1$ is an $\ell = 2$, $k = 10$ mode ($m = 0$ occurs at 293.7 s), while $f_2$ is an $\ell = 2$, $k = 8$ mode ($m = 0$ occurs at 255.0 s). This WD model has a stellar mass of 0.720 $M_\odot$, an effective temperature $T_{\text{eff}} = 11,610$ K, an He envelope mass of $M_{\text{He}}/M_* = 10^{-2.0}$, and an H envelope mass of $M_{\text{H}}/M_* = 10^{-4.5}$.

Additionally, we can use our spectroscopic constraints to explore the models of Romero et al. (2012) of a 0.705 $M_\odot$, 11,810 K WD with a thick ($10^{-4.445} M_\odot$) hydrogen layer mass. Similarly, we find that the 292.9 s mode is either an $\ell = 2$, $k = 10$ or $\ell = 1$, $k = 5$ mode. The 255.7 s mode is either an $\ell = 2$, $k = 8$ or $\ell = 1$, $k = 4$ mode. We caution that because these solutions are consistent does not imply they are correct—our assumptions may not indeed be valid. But these solutions will help inform our analysis of what could be causing the rapid period change in WD 0111+0018.

Using our spherical degree ($\ell$) identifications described in Section 4.1, we can break the degeneracy in $f_1$ and suggest that the 292.9 s periodicity represents an $\ell = 1$, $k = 5$ mode, while the 255.7 s periodicity is an $\ell = 2$, $k = 8$ mode. In order to visualize how each such mode samples the star, we have included a propagation diagram in Figure 5. We have marked where a $\sim 250$ s and a $\sim 300$ s $g$-mode for different $\ell$ values would probe the star (where $\sigma^2 < N^2$, $L_1^2$).

However, an even more informative display of how each mode could probe the star differently can be found in Figure 6. Here we plot, as a function of the “normalized buoyancy radius” (see Montgomery et al. 2003), the weight functions for $N^2$ (see Equation (8c) of Kawaler et al. 1985) for our best identifications of the modes in WD0111+0018. The weight function essentially shows where in the star an excited pulsation is most resonant; it shows the sensitivity of a mode’s period to changes in the equilibrium model.

Immediately evident from this exercise is that the majority of the energy of the 292.9 s mode, $f_1$, is located in the He layer or the region of the He–H transition. Conversely, nearly all the energy of the 255.7 s mode, $f_2$, is resonant much deeper in the star, inside the C/O–He transition. This suggests that the 255.7 s mode energy is predominantly resonant inside the core,

themselves. For instance, the depth of the convection zone
represented by the fast rate of change of period with time in
the outer layer of the star, one possibility for the new timescale
large difference in rates of period change between the two.

We can investigate how each pulsation samples the star by plotting
a weight function (WFₖ) for each mode. The top panel shows the chemical
transition zones as a function of depth in the star. The bottom two panels show
the weight functions for our best models (which are only marginally constrained)
to represent f₁ and f₂, respectively. All plots are shown as a function of the
“normalized buoyancy radius,” Φ(r), described in Montgomery et al. (2003),
where 0 is the center and 1 is the surface of the WD. The corresponding mass
fraction is shown at the top of this figure.

(A color version of this figure is available in the online journal.)

while the 292.9 s mode samples significantly more of the surface
layers of the star. The 255.7 s mode would therefore be much
less sensitive to changes in the outer regions of the WD.

4.4. Additional Mechanisms for Rapid Period Change

Given the insensitivity of the 255.7 s mode to changes in the outer layer of the star, one possibility for the new timescale represented by the fast rate of change of period with time in WD 0111+0018 involves a change in the surface layers of the star at a rate much faster than from cooling alone but much slower than the timescales associated with the pulsations themselves. For instance, the depth of the convection zone of the WD could change gradually, perhaps as a result of a change in the global magnetic field of the WD. We have seen evidence for rapid changes in the pulsation profile of WDs in the past; especially notable is the so-called sforzando event seen in GD 358 in 1996, in which this DBV changed from a highly multi-periodic pulsation spectrum to a higher-amplitude, monoperiodic pulse shape, indicating a rapid thinning of the convection zone during this event (Provencal et al. 2009; Montgomery et al. 2010).

We have investigated the plausibility of this scenario by comparing two slightly different theoretical models. Both model WDs have identical masses (0.71 M☉), effective temperatures (11,810 K), and chemical profiles. However, we have changed the efficiency of convection by varying the mixing length parameter: in our initial model we use ML2/α = 1.23 and in the other we use ML2/α = 1.12. This effectively, albeit superficially, causes the second model to have a slightly thinner convection zone.

We take the difference of the periods computed by the first model with the periods from the second to estimate the effect these changes would have on different modes. We find that even the shortest period ℓ = 1, k = 1 pulsations would change in mode period by more than 1 ms from one model to the next. This result can reproduce the observed rates of period change in WD 0111+0018 if the timescale of this change in the depth of the convection zone acts on the order of a few decades.

One way to perturb the overall depth of the convection zone is to introduce a gradual change in the global magnetic field strength. In fact, increasing the global magnetic field from 0 G to 1 kG would effectively change the depth of the convection zone by the same amount as changing the convective efficiency from ML2/α = 1.23 to ML2/α = 1.12 (M. H. Montgomery & E. T. Vishniac, in preparation). It is possible then that the rapid period change we observe in WD 0111+0018 could be related to a secular (or long-term periodic) change in the strength of the magnetic field in the star. If this is indeed a by-product of a stellar cycle, we might expect our heretofore secular increase to at some point turn over or in fact become discontinuous when the magnetic cycle changes course. Future observations of WD 0111+0018 will help constrain this hypothesis.

Another mechanism that could affect one mode differently than another, in the way we see in WD 0111+0018, is a changing rotation rate. Rotation will act to break spherical symmetry, splitting non-radial pulsations into (2ℓ + 1) azimuthal components that would normally be degenerate with the m = 0 component (Hansen et al. 1977). However, if the rotation rate were somehow to change (a spin-up or spin-down), only the m ≠ 0 components would be affected. If f₁ is an m = ±1 mode and f₂ is an m = 0 mode, a changing rotation rate could explain the large difference in rates of period change between the two.

Our observed rate of change of period with time for f₁ would require the rotation of the WD to change at a rate |P₉rot| > 0.3 s yr⁻¹. Such a rapid change would require a tremendous reservoir of angular momentum to redistribute, and some place to deposit this energy. This appears especially unlikely given the observational result that the hot pulsating white dwarf PG 1159-035 rotates as a solid body through more than 97.5% of its mass, indicating that WDs have very little angular momentum, even at T eff > 80,000 K (Charpinet et al. 2009).

Unfortunately, we do not observe any other multiplet components for f₁ or f₂, making it difficult to definitively rule out this rotational effect.⁶ But our results from the convective light curve fitting discussed in Section 4.1 did yield predictions for the m value of each mode: m = 0 for f₁ and m = 0, ±1 for f₂. This contradicts the values needed to invoke a changing rotation rate to explain the different rates of period change between these modes.

Some additional effects intrinsic to the star that could cause phase variations include linear interference (such as beating of closely spaced modes), nonlinear interactions with other modes (such as mode coupling), and a precession of the rotation axis with our line of sight (Winget et al. 1990). Each of these cases would simultaneously affect the amplitude of a given mode. Since we do not see evidence of the amplitudes evolving identically with the phase (comparing Figure 2 with Figure 3).

⁶ Due to inclination effects, it is not uncommon to see an m = ±1 component of a rotationally split multiplet and not the m = 0 central component. This is well illustrated for different ℓm values in Figure 1 of Brassard et al. (1995). It is also possible that only one component of a multiplet is excited.
none of these are likely responsible for the inferred high rates of period change in WD 0111+0018.

5. CONCLUSIONS

As part of a search for substellar companions to isolated WDs, we have discovered a DAV, WD 0111+0018, with an unexpectedly fast rate of change of period with time. We see this anomalously high rate reflected in not only the highest-amplitude mode in the star at 292.9 s but also the two nonlinear combination frequencies that sample this parent mode. All three of these are not independent pulsation modes but rather interactions of exotic weakly interacting particles such as axions to anomalies in the rate of change of period with time of DAVs.

We have attempted to use the nonlinear combination frequencies present in this star as probes of the spherical degree of the two parent modes. Using convective light curve fitting (Montgomery 2005), we find that the 292.9 s mode is best represented as an $\ell = 1$, $m = 0$ mode and that the $f_2$ parent mode at 255.7 s best fits as an $\ell = 2$, $m = \pm 1$ mode. This identification, if confirmed, would rule out a changing rotation rate as the explanation of the rapid period change in the 292.9 s mode.

Guided by the spherical degrees we identify by this convective light curve fitting we found a best-fit asteroseismic model, which is admittedly poorly constrained. Still, this exercise suggests that $f_1$ is an $\ell = 1$, $k = 3$ and that $f_2$ is an $\ell = 2$, $k = 8$ mode. We construct a weight function, and show that this solution for $f_2$ is almost entirely resonant inside the core, and is thus much less sensitive than $f_1$ to changes in the outer regions of the WD.

We discuss a scenario where a gradual thinning of the convection zone could be responsible for the rapid rates of period change observed in this DAV. This thinning could be caused by increasing the global magnetic field by less than 1 kG over a decade. Such a hypothesis is hard to test empirically, although if this magnetic field change is related to a stellar magnetic activity cycle, we would expect an eventual turnover or discontinuity in the observed $(O-C)$ diagram.

Independent of the cause of this unexpected period change, we have for the first time shown that the evolution of nonlinear combination frequencies in a DAV matches the evolution of their parent modes. This behavior confirms that these combination frequencies are not independent pulsation modes but rather artifacts from some nonlinear distortion occurring in the star.

We are especially grateful to all those whose time in West Texas made this result possible: S. E. Thompson, C. M. Yeates, K. I. Winget, Davis Winget, R. E. Nather, Elizabeth J. Jeffery, Ross E. Falcon, and G. F. Miller. We thank E. L. Robinson, Anjum S. Mukadam, Denis Sullivan, and Ross E. Falcon for helpful discussions, and acknowledge the McDonald Observatory staff for tireless support, especially Dave Doss and John Kuehne. This work is supported by the Norman Hackerman Advanced Research Program, under grants 003658-0255-2007 and 003658-0252-2009, by a grant from the NASA Origins Program, NAG5-13094, and by the National Science Foundation, under grant AST-0909107.
