Abstract:
Future hadron collider experiments are expected to record large to huge samples of $tt$ events. The analysis of these data with respect to $tt$ spin-spin correlations requires precise predictions of the production of these quark pairs in a general spin configuration. Therefore we have computed, at next-to-leading order (NLO) in the QCD coupling, the spin density matrices describing $tt$ production by quark antiquark annihilation, which is the dominant production process at the Tevatron. Moreover we have computed the strength of the $tt$ spin correlation at NLO, using various spin quantization axes.

Pairs of top and antitop quarks will be produced copiously with the upgraded Fermilab Tevatron collider and in even larger numbers with the Large Hadron Collider (LHC) at CERN, allowing for detailed investigations of the properties of these quarks in the future. For this aim the study of top spin phenomena will play an important role. This is because the top quark, as compared with lighter quarks, is unique in that it is sufficiently short-lived to prevent hadronization effects from diluting the spin-polarisations and spin-spin correlations that were imprinted upon the $t$ and $\bar{t}$ quarks by their production mechanism. Hence spin-polarization and spin-correlation phenomena will provide valuable information about the interactions of top quarks.

An attempt to detect these spin correlations in a small $t\bar{t}$ dilepton sample collected at the Tevatron was recently reported by the D0 collaboration [1].

Needless to say, in order to interpret future data, the predictions of these spin phenomena should be as precise as possible. Within the Standard Model (SM) top antitop pair production at hadron colliders is determined by QCD. So far the next-to-leading order (NLO) QCD corrections are known for the spin-averaged differential $t\bar{t}$ cross section [2, 3, 4, 5], while spin correlations were analysed only to leading order [6, 7, 8, 9, 10, 11] in $\alpha_s$. In this letter we report on progress in providing a complete description of these spin effects within QCD at NLO: We have computed, as a first step in this direction, the $t\bar{t}$ spin density matrices for the parton reactions $q\bar{q} \to t\bar{t}, t\bar{g}$ to order $\alpha_s^3$. We have also calculated, for these reactions, the degree of the $t\bar{t}$ spin correlation at NLO for different $t$ and $\bar{t}$ spin quantization axes.

At the Tevatron $q\bar{q}$ annihilation is the dominant process for producing top quark pairs while at the LHC $t\bar{t}$ production is mainly due to gluon gluon fusion. The $t\bar{t}$ spin correlations and spin polarisations can be inferred from appropriate angular correlations and distributions of the $t$ and $\bar{t}$ decay products. In the SM the main top decay modes are $t \to bW \to bq' \bar{q}, b\ell \nu$. Among these final states the charged leptons, or the jets from quarks of weak isospin $-1/2$ originating from $W$ decay, are most sensitive to the polarisation of the top quarks. Hence to leading order in the QCD coupling one has to treat the two parton reactions

$$ gg, q\bar{q} \to t\bar{t} \to b\bar{b} + 4f, $$

where $f = q, \ell, \nu$. The amplitudes for these two- to six-body processes, with intermediate top quarks of non-zero total width, were given first in [12]. The computation of the NLO QCD corrections to these amplitudes is quite a demanding task [4]. In view of the fact that the total width $\Gamma_t$ of the top quark is much smaller than its mass, $\Gamma_t/m_t = \mathcal{O}(1\%)$, one may however analyse these reactions using the so-called narrow width or leading pole approximation [13, 14]. In our case this approach consists, for a given process, in an expansion of the amplitude around the poles of the unstable $t$ and $\bar{t}$ quarks, which amounts to an expansion in powers of $\Gamma_t/m_t$. Only the leading term of this expansion, i.e., the residue of the double poles is considered.

\footnote{At NLO, apart from the gluon radiation reactions, the processes $g + q(\bar{q}) \to t\bar{t} + q(\bar{q}) \to b\bar{b} + 4f + q(\bar{q})$ must also be taken into account.}
here. Then the radiative corrections to (1) can be classified into so-called factorisable and non-factorisable corrections. The non-factorisable NLO QCD corrections were calculated in [15]. For the factorisable corrections the square of the complete matrix element $M^{(\lambda)}$ is of the form

$$|M^{(\lambda)}|^2 \propto \text{Tr} \left[ \rho R^{(\lambda)} \tilde{\rho} \right] = \rho_{\alpha'\alpha} R^{(\lambda)}_{\alpha\alpha',\beta\beta'} \tilde{\rho}_{\beta'\beta}. \tag{2}$$

Here $R^{(\lambda)}$ denotes the density matrix for the production of on-shell $t\bar{t}$ pairs, the label $\lambda$ indicates the process, and $\rho, \tilde{\rho}$ are the density matrices describing the decay of polarised $t$ and $\bar{t}$ quarks, respectively, into specific final states. The subscripts in (2) denote the $t, \bar{t}$ spin indices. Note that both the production and decay density matrices are gauge invariant.

The one-loop QCD corrections to the semileptonic decays of polarised top quarks and to $t \to W + b$ can be extracted from the results of [16] and [17, 18], respectively. In the following we describe our computation of the density matrices for $t\bar{t}$ production by $q\bar{q}$ annihilation. At NLO we have to consider the reactions

$$q(p_1) + \bar{q}(p_2) \to t(k_1) + \bar{t}(k_2), \tag{3}$$

and

$$q(p_1) + \bar{q}(p_2) \to t(k_1) + \bar{t}(k_2) + g(k_3). \tag{4}$$

We define the production density matrix for the process (3) in terms of its transition matrix element as follows: (for ease of notation we omit the label $\lambda$ in the following)

$$R_{\alpha\alpha',\beta\beta'} = \frac{1}{N_{qq}} \sum_{\text{colors}} \sum_{\text{initial spins}} \langle t_\alpha \bar{t}_\beta | T | q\bar{q} \rangle \langle q\bar{q} | T^\dagger | t_{\alpha'} \bar{t}_{\beta'} \rangle, \tag{5}$$

where the factor $N_{qq} = (2N_C)^2 = 36$ averages over the spins and colors of the initial $q\bar{q}$ pair. The matrix structure of $R$ is

$$R_{\alpha\alpha',\beta\beta'} = A \delta_{\alpha\alpha'} \delta_{\beta\beta'} + B_i (\sigma^i)_{\alpha\alpha'} \delta_{\beta\beta'} + \bar{B}_i \delta_{\alpha\alpha'} (\sigma^i)_{\beta\beta'} + C_{ij} (\sigma^i)_{\alpha\alpha'} (\sigma^j)_{\beta\beta'}, \tag{6}$$

where $\sigma^i$ are the Pauli matrices. Using rotational invariance the ‘structure functions’ $B_i, \bar{B}_i$ and $C_{ij}$ can be further decomposed. The function $A$, which determines the $t\bar{t}$ cross section, is known to next-to-leading order in $\alpha_s$ from the work of [2, 3]. Because of parity (P) invariance the vectors $B, \bar{B}$ can have, within QCD, only a component normal to the scattering plane. This component, which amounts to a normal polarisation of the $t$ and $\bar{t}$ quarks, is induced by the absorptive part of the scattering amplitude, and it was computed for $q\bar{q}$ and $gg$ initial states in [19, 20] to order $\alpha_s^3$. The normal polarisation is quite small, both for $t\bar{t}$ production at the Tevatron and at the LHC. Parity and CP invariance of QCD dictates that the
functions $C_{ij}$, which encode the correlation between the $t$ and $\bar{t}$ spins, have the structure

$$C_{ij} = c_1 \delta_{ij} + c_2 \hat{p}_i \hat{p}_j + c_3 \hat{k}_{1i} \hat{k}_{1j} + c_4 (\hat{k}_{1i} \hat{p}_j + \hat{p}_i \hat{k}_{1j}),$$

(7)

where $\hat{p}_1$ and $\hat{k}_1$ are the directions of flight of the initial quark and of the $t$ quark, respectively, in the parton c.m. frame. The production density matrix for the reaction (4) can be defined and decomposed in an analogous fashion.

To Born approximation the functions $c_r$ were given, e.g., in [7]. In order to determine these functions to order $\alpha_s^3$ we first computed the one-loop diagrams that contribute to (3). Dimensional regularization was employed to treat both the ultraviolet and the infrared and collinear singularities which appear in the diagrams. The ultraviolet singularities were removed by using the $\overline{\text{MS}}$ prescription for the QCD coupling $\alpha_s$ and the on-shell definition of the top mass $m_t$. The initial quarks are taken to be massless. After renormalisation the density matrix for the $t\bar{t}$ final state still contains single and double poles in $\epsilon = (4 - D)/2$ due to soft and collinear singularities. These poles are cancelled after including the contributions of the reaction (4) and mass factorization. For the latter we used the $\overline{\text{MS}}$ factorization scheme. We avoided the computation of the exact density matrix for the reaction (4) in $D$ dimensions by employing a simple version of the phase-space slicing method [22, 23]: We divided the phase space into four regions, namely the region where the gluon is soft, the two regions where the gluon is collinear to one of the initial state massless quarks (but not soft), and the complement of these three regions, where all partons are 'resolved'. This decomposition can be performed using a single dimensionless cut parameter $x_{\text{min}}$. For example, the soft region is defined by the requirement that the scaled gluon energy in the c.m. system $x_g = 2E_g/\sqrt{s}$ is smaller than $x_{\text{min}}$. In the soft region we used the eikonal approximation of the matrix element for reaction (4) and the soft limit of the phase space measure. The integration over the gluon momentum can then be carried out analytically in $D$ dimensions. The two collinear regions are defined by $(\cos \theta_{qg} > (1 - x_{\text{min}})$ and $x_g > x_{\text{min}})$ and $(\cos \theta_{qg} < (-1 + x_{\text{min}})$ and $x_g > x_{\text{min}})$, respectively, where $\theta_{qg}$ is the angle between the gluon and the quark in the $q\bar{q}$ c.m. frame. In these regions we used the collinear approximations for both the squared matrix element and the phase space in $D$ dimensions. Finally, the exact spin density matrix for reaction (4) in four space-time dimensions was used in the resolved region, where all necessary phase space integrations can be carried out numerically. By construction, all four individual contributions depend logarithmically on the slicing parameter $x_{\text{min}}$, but in the sum only a residual linear dependence on $x_{\text{min}}$ remains, which is due to the approximations made in the soft and collinear regions. By varying $x_{\text{min}}$ between $10^{-3}$ and $10^{-8}$ we checked that for $x_{\text{min}} \leq 10^{-4}$ this residual dependence is smaller than our numerical error (which is less than a permill for all results discussed below).

After mass factorisation we are left with finite density matrices for the $t\bar{t}$ and the $t\bar{t}$ + hard gluon final states. As a check of our calculation we first compute the total cross section for $q\bar{q} \rightarrow t\bar{t} + X$ at NLO. If one identifies the $\overline{\text{MS}}$ renormalisation scale
μ with the mass factorisation scale μ_F and neglects all quark masses except for m_t, then one can express the cross section in terms of dimensionless scaling functions [4]:

$$\tilde{\sigma}_{qq}(\hat{s}, m_t^2) = \frac{\alpha^2}{\mu^2} \left[ f_{q\bar{q}}^{(0)}(\eta) + 4\pi\alpha_s f_{q\bar{q}}^{(1)}(\eta) + \tilde{f}_{q\bar{q}}^{(1)}(\eta) \ln(\mu^2/m_t^2) \right], \quad (8)$$

where \(\hat{s}\) is the parton c.m. energy squared and \(\eta = \hat{s}/4m_t^2 - 1\). We have compared our result for \(\sigma_{qq}\) as a function of \(\eta\) with those of [4, 5] and found perfect agreement.

We now consider the following set of spin-correlation observables:

$$\mathcal{O}_1 = 4 \mathbf{s}_1 \cdot \mathbf{s}_2, \quad (9)$$

$$\mathcal{O}_2 = 4 (\hat{\mathbf{k}}_1 \cdot \mathbf{s}_1)(\hat{\mathbf{k}}_2 \cdot \mathbf{s}_2), \quad (10)$$

$$\mathcal{O}_3 = 4 (\hat{\mathbf{p}}_1 \cdot \mathbf{s}_1)(\hat{\mathbf{p}}_2 \cdot \mathbf{s}_2), \quad (11)$$

$$\mathcal{O}_4 = 4 (\hat{\mathbf{p}}_2^* \cdot \mathbf{s}_1)(\hat{\mathbf{p}}_1^{**} \cdot \mathbf{s}_2), \quad (12)$$

$$\mathcal{O}_5 = 4 (\hat{\mathbf{d}}_1 \cdot \mathbf{s}_1)(\hat{\mathbf{d}}_2 \cdot \mathbf{s}_2), \quad (13)$$

where \(\mathbf{s}_1, \mathbf{s}_2\) are the \(t\) and \(\bar{t}\) spin operators, respectively. The factor of 4 is conventional. With this normalization, the expectation value of \(\mathcal{O}_1\) is equal to 1 at the Born level. The expectation values of the observables (10), (11), (12), and (13) determine the correlation of different \(t, \bar{t}\) spin projections. Eq. (10) corresponds to a correlation of the \(t\) and \(\bar{t}\) spins in the helicity basis, while (11) correlates the spins projected along the beam line in the parton c.m.s. The ‘beam-line basis’ used in (12) was defined in [9] and refers to spin axes being parallel to the antiquark direction in the \(t\) rest frame \(\hat{\mathbf{p}}_2^*\) and to the quark direction in the \(\bar{t}\) rest frame \(\hat{\mathbf{p}}_1^{**}\), respectively. The spin axes \(\hat{\mathbf{d}}_{1,2}\) in (14) correspond to the so-called ‘optimal basis’ [24, 10] to be discussed below.

For quark-antiquark annihilation it turns out that the spin correlation (11) [7, 11] and the correlation in the beam-line basis (12) [9] are stronger than the correlation in the helicity basis. A spin-quantization axis was constructed in [24, 10] with respect to which the \(t\) and \(\bar{t}\) spins are 100% correlated to leading order in the QCD coupling, for all energies and scattering angles. In terms of the structure functions of (6) this means that the ‘optimal’ spin axis \(\hat{\mathbf{d}}\) fulfills the condition

$$\hat{d}_i C_{ij} \hat{d}_j = A. \quad (14)$$

The existence of a solution of Eq. (14) is a special property of the leading order spin density matrix for the reaction \(q\bar{q} \rightarrow t\bar{t}\). One finds [24, 10]:

$$\hat{d} = \frac{-\hat{\mathbf{p}}_1 + (1 - \gamma_1)(\hat{\mathbf{p}}_1 \cdot \hat{\mathbf{k}}_1)\hat{\mathbf{k}}_1}{\sqrt{1 - (\hat{\mathbf{p}}_1 \cdot \hat{\mathbf{k}}_1)^2 (1 - \gamma_1^2)}}, \quad (15)$$

4
where $\gamma_1 = E_1/m_t$. The construction of this axis explicitly uses the leading order result for the spin density matrix, and different generalizations to higher orders are possible. We use in (13) as spin axes:

$$
\hat{d}_1 = \hat{d},
$$

$$
\hat{d}_2 = \frac{-\hat{p}_1 + (1 - \gamma_2)(\hat{p}_1 \cdot \hat{k}_2)\hat{k}_2}{\sqrt{1 - (\hat{p}_1 \cdot \hat{k}_2)^2(1 - \gamma_2^2)}},
$$

(16)

where $\gamma_2 = E_2/m_t$. For the 2 to 2 process $q\bar{q} \rightarrow t\bar{t}$, $\hat{d}_2 = \hat{d}_1 = \hat{d}$. (A different generalization of $\hat{d}$ to higher orders was used in [25].)

The expectation value of a spin-correlation observable $\mathcal{O}$ at parton level can be written at next-to-leading order in analogy to (8) as follows:

$$
\langle \mathcal{O} \rangle_{q\bar{q}} = g^{(0)}_{q\bar{q}}(\eta) + 4\pi\alpha_s(g^{(1)}_{q\bar{q}}(\eta) + \tilde{g}^{(1)}_{q\bar{q}}(\eta) \ln(\mu_F^2/m_t^2)).
$$

(17)

Note that these quantities depend explicitly on the factorization scale $\mu_F$, but only implicitly (through $\alpha_s$) on the renormalization scale $\mu$. This is because a factor $\alpha_s^2$ drops out in the expectation values, and hence the Born result is of order $\alpha_s^0$.

Our results for the functions $g^{(0)}_{q\bar{q}}(\eta)$, $g^{(1)}_{q\bar{q}}(\eta)$ and $\tilde{g}^{(1)}_{q\bar{q}}(\eta)$ are shown for the five observables (9)-(13) in Figs. 1-5. In each figure, the dotted line is the Born result $g^{(0)}_{q\bar{q}}(\eta)$, the full line shows the function $g^{(1)}_{q\bar{q}}(\eta)$, and the dashed line is $\tilde{g}^{(1)}_{q\bar{q}}(\eta)$. A general feature of all results is that the QCD corrections are very small for values of $\eta \lesssim 1$. For larger values of $\eta$, the functions $g^{(1)}_{q\bar{q}}(\eta)$ depart significantly from zero. Also, the functions $\tilde{g}^{(1)}_{q\bar{q}}(\eta)$ become nonzero, with less dramatic growth as $\eta \rightarrow \infty$ and with an opposite sign as compared to $g^{(1)}_{q\bar{q}}(\eta)$. The phenomenological implications of these features for spin correlations at the Tevatron and the LHC will be studied in detail in a future work. Here we merely note that the substantial QCD corrections for large $\eta$ will be damped by the parton distribution functions, which decrease rapidly with $\eta$. Moreover, at Tevatron energies values of $\eta$ above $\sim 30$ are kinematically excluded.

To summarize: We have computed the spin density matrices describing $t\bar{t}$ production by $q\bar{q}$ annihilation to order $\alpha_s^3$. Further we have evaluated the scaling functions encoding the QCD corrections to spin correlations, using a number of different spin quantization axes. This work provides a building block, which was missing so far, towards a complete description of spin effects in the hadronic production of top quark pairs at NLO in the strong coupling.
