ABSTRACT

Context. Molecular hydrogen (H₂) is the most abundant molecule in the circumstellar (CS) environments of young stars, and is a key element in giant planet formation. The measurement of the H₂ content provides the most direct probe of the total amount of CS gas, especially in the inner warm planet-forming regions of the disks.

Aims. Most Herbig Be stars (HBes) are distant from the Sun and their nature and evolution are still debated. We therefore conducted mid-infrared observations of H₂ as a tracer of warm gas around HBes known to have gas-rich CS environments.

Methods. We report a search for the H₂ S(1) emission line at 17.0348 μm in the CS environments of 5 HBes with the high resolution spectroscopic mode of VISIR (ESO VLT Imager and Spectrometer for the mid-InfraRed).

Results. No source shows evidence for H₂ emission at 17.0348 μm. Stringent 3σ upper limits on the integrated line fluxes are derived. Depending on the adopted temperature, limits on column densities and masses of warm gas are also estimated. These non-detections constrain the amount of warm (>150 K) gas in the immediate CS environments of our target stars to be less than ∼1–10 M⊕.

Key words. stars: circumstellar matter – stars: formation – stars: pre-main sequence – ISM: molecules

1. Introduction

Molecular hydrogen (H₂) is the most abundant molecule in the environment of young stars. It remains optically thin up to high column densities (∼10²³ cm⁻²), and does not freeze onto dust grain surfaces. It furthermore self-shields efficiently against photodissociation by far-ultraviolet (FUV) photons. Therefore, H₂ is the only molecule that can directly constrain the mass reservoir of molecular gas in the circumstellar (CS) environment of pre-main sequence stars. On the other hand, H₂ is one of the most challenging molecules to detect. Electronic transitions occur in the UV to which the Earth’s atmosphere is opaque, and rotational and rovibrational transitions at infrared (IR) wavelengths are faint because of their quadrupolar origin. FUV spectroscopic observations of H₂ absorption lines have provided evidence for the presence of cold and warm excited H₂ around numerous Herbig Ae/Be stars (HAEs) but have not allowed us to determine the spatial distribution of the observed gas (e.g. Martin-Zaïdi et al. 2008).

Detections of H₂ line emission from disks around young stars with ISO (Thi et al. 2001) were contradicted by ground-based observations (Richter et al. 2002; Sako et al. 2005), which showed that the observed emission could be due to the surrounding cloud material. Carmona et al. (2008) modeled the mid-IR H₂ lines originating in a gas-rich disk, seen face-on, surrounding a Herbig Ae (HAE) star at 140 pc from the Sun. By assuming that the gas and dust were well-mixed in the disk, a gas-to-dust ratio of about 100, and that $T_{\text{gas}} = T_{\text{dust}}$, those authors demonstrated that mid-IR H₂ lines could not be detected with the existing instruments. Indeed, they were unable to detect any H₂ mid-IR emission line in their sample of 6 HAE stars.

At the present time, observations of H₂ mid-IR emission lines have been reported in 8 of 76 T Tauri stars observed with Spitzer (Lahuis et al. 2007). Although mid-IR windows are strongly affected by sky and instrument background emission, the advent of high spectral and spatial resolution spectrographs allows us to study the H₂ emission from the ground, as demonstrated in the cases of two HAEs, HD 97048 (Martin-Zaïdi et al. 2007) and AB Aur (Binner et al. 2007), for which particular conditions are required in their CS disks. The analyses of these data usually assumes that the H₂ excitation is in local thermodynamic equilibrium (LTE) and can thus be characterized by a single excitation temperature, which should be close to the gas temperature because of the low critical densities. The AB Aur observations infer an H₂ gas temperature that is significantly higher than the dust temperature.

In contrast to HAEs, the more distant Herbig Be stars (HBs) earlier than B9 type have been poorly studied. As a consequence, the nature and evolution of the CS material surrounding HBs is still a subject of controversy. The Spectral Energy Distributions (SEDs) are very different from one HBe to another (e.g. Hillenbrand et al. 1992). Some have SEDs that are comparable to those observed for HAes, and have been classified as group I or group II stars haboring disks according to the classification of Meeus et al. (2001). However, numerous HBE SEDs with little IR excess have been modeled successfully by

Article published by EDP Sciences
free-free-free emission originating in a gaseous CS envelope, and compared with rapidly rotating classical Be stars. In addition, the mid-IR emission observed in HBe stars is generally not confined to optically thick disks but originates in more complex environments such as remnant envelopes or halos (Leinert et al. 2001; Polomski et al. 2002; Vinković et al. 2006). This implies that there are structural differences between HAEs and the more luminous HBe stars (Natta et al. 2000; Leinert et al. 2001). These results are fully consistent with the more rapid evolution of the more massive massive HAEs, which should still be partially embedded in their natal cloud. On the other hand, near-IR interferometric data of HBe stars have been interpreted using flared disks models (e.g. Kraus et al. 2007).

We selected five HBe stars whose CS environments are rich in gas as observed by the FUSE satellite (Martin-Zaïdi et al. 2008). The selected stars have IR excesses that are assumed to represent the presence of CS dusty disks (e.g. Hillenbrand et al. 1992; Polomski et al. 2002), but the disk scenario has not yet been clearly established. The aim of our study is to detect the H2 pure rotational emission line at 17.0348 μm in the vicinity of these stars with the high resolution mode of the VLT/VISIR spectrograph (Lagage et al. 2004) and constrain the warm CS gaseous component.

### 2. Selection of the target stars

The selection of the five target stars was motivated by the previous observations of H2 electronic lines in the FUV spectral range, which showed that the CS environments of HBe stars are rich in cold and warm H2 (Martin-Zaïdi et al. 2008). The detection of H2 absorption lines provided evidence for the presence of cold (\sim 100 K) and warm/hot CS gas (up to 1500 K) around these stars. We first briefly describe the CS environments of each of the five sample stars. The main astrophysical parameters of the stars are summarized in Table 1.

**Table 1.** Astrophysical parameters of the sample stars (Cols. 2 to 6). $v_{\text{rad}}$ is the radial velocity of the star in the heliocentric rest frame. Columns 7 to 12 summarize the observations. The airmass and seeing intervals are given from the beginning to the end of the observations.

| Star         | Sp. Type | $T_{\text{eff}}$ (K) | $A_v$ (mag) | $v_{\text{rad}}$ (km s$^{-1}$) | $d$ (pc) | $t_{\text{exp}}$ (s) | Airmass | Optical Seeing (°) | Standard Star | Airmass | Optical Seeing (°) |

**HD 250550 and HD 259431:** The selection of the five target stars was motivated by the previous observations of H2 electronic lines in the FUV spectral range, which showed that the CS environments of HBe stars are rich in cold and warm H2 (Martin-Zaïdi et al. 2008). The detection of H2 absorption lines provided evidence for the presence of cold (\sim 100 K) and warm/hot CS gas (up to 1500 K) around these stars (Martin-Zaïdi et al. 2008). Our preliminary analysis of its spectrum displayed broad, but relatively weak [O I] emission profiles, which cannot originate in the dusty disk surface but possibly in a rotating gaseous disk inside the dust-sublimation radius (Acke et al. 2005). Our preliminary analysis of its FUSE spectrum indicates that the CS environment of this star is rich in H2. The excitation of H2 appears to be similar to the HBe stars observed by Martin-Zaïdi et al. (2008). The modeling of the excitation conditions with the Meudon PDR Code (Le Petit et al. 2006) allows us to conclude that the observed gas is probably located in the remnant cloud where the star formed. We emphasize that no H2 mid-IR line was detected by the Spitzer Space Telescope towards this star (Lahuis et al. 2007).

**HD 76534:** Hillenbrand et al. (1992) analyzed the SED of HD 76534 and stressed that the low near-IR excess was probably due to free-free-free emission in an ionized envelope rather than CS dust. By analyzing FUV absorption lines of H2 and deriving the excitation conditions of the gas around the star, Martin et al. (2004) concluded that the CS environment of HD 76534, which is a B2 star, is probably too hostile for the presence of a CS disk.

**HD 45677:** The measured infrared excess was attributed to a dust shell surrounding HD 45677 by Swings & Allen (1971). The presence of a disk was inferred by polarization and UV spectroscopic measurements of accreting gas (Schulte-Ladbeck et al. 1992; Grady et al. 1993); these studies also agreed with the presence of an actively accreting CS disk around the star. The presence of such a disk is confirmed by the analysis of emission lines from ionized metals by Muratorio et al. (2006). Our preliminary analysis of the FUSE spectrum of this star shows the presence of two or more gaseous components along the line of sight. This may be consistent with the presence of a disk associated with a CS envelope.

### 3. Observations and data reduction

Searches for mid-IR H2 lines can be undertaken with the ESO/VISIR instrument due to its high spectral and spatial resolution. Its high spectral resolution (10 000 < R < 30 000) allows us to disentangle the H2 lines from the absorption lines due to the Earth’s atmosphere. VISIR offers access to the most intense pure rotational lines of H2: the S(1) line at 17.0348 μm, S(2) at 12.2786 μm, S(3) at 9.6649 μm, and S(4) at 8.0250 μm. The S(0) transition close to 28 μm is not observable from the ground due to the Earth’s atmospheric absorption, and the S(3) line, which is located amidst a forest of telluric ozone features, is only observable for particularly favorable Doppler shifts.
Fig. 1. Spectra obtained for the H$_2$ S(1) line at 17.0348 μm. Top panel: continuum spectra of the standard star and of the target before telluric correction. Central panel: full corrected spectra: dotted lines show spectral regions strongly affected by telluric features. Bottom panel: zoom of the region where the S(1) line should be observed (dashed vertical lines). A Gaussian of width FWHM = 21 km s$^{-1}$ and integrated line flux equal to the 3σ line-flux upper limits is overplotted. The spectra were corrected neither for the radial velocity of the targets nor the Earth’s rotation velocity.

The five sample stars were observed with the high spectral resolution long-slit mode of VISIR on January 15 and 16, 2006. The central wavelength of the observations was set to be 17.035 μm. We used the 0.75′′ slit, providing a spectral resolution of about 14,000. The details of the observation conditions are summarized in Table 1. According to its IRAS fluxes, HD 76534 should be observable in the spectral range of VISIR. However, during the observation, the mid-IR flux of this star appeared to be very low and the resulting spectrum could not be used to complete an accurate analysis.

For all other observations, the standard “chopping and nodding” technique was used to suppress the large sky and telescope background dominating at mid-IR wavelengths (for details of the observation technique see Martin-Zaïdi et al. 2007). The chopping was performed with a 8′′ amplitude, which enabled us to detect the gas of any elongated structure around our targets. To correct the spectrum for the Earth atmospheric absorption and to obtain the absolute flux calibration, we observed standard stars immediately before and after observing our sources. Since the HD 76534 and HD 98922 spectra have far higher signal-to-noise (S/N) ratios than that of the standard stars, we divided the spectra of HD 98922, HD 250550, and HD 259431 by that of HD 45677, and divided the spectrum of HD 45677 by that of HD 98922, to correct for the telluric absorption. We checked that the Doppler shifts were sufficiently different from one star to the other, to ensure that the analysis would not be significantly affected. We used the observed and modeled spectra of the standard stars (Cohen et al. 1999) to derive the absolute flux calibration. The wavelength calibration was completed by fitting the observed sky background features with a model of Paranal’s atmospheric emission. The spectra were not corrected for dust extinction, which is negligible in the mid-IR for $A_v < 40$ mag (Fluks et al. 1994).

4. Data analysis
For the four high S/N spectra of stars in our sample, we display in Fig. 1, the spectra of the standard stars overplotted on the target spectra (top panel), the entire atmosphere-corrected spectra before the flux calibration (central panel), and the region of the flux-calibrated atmosphere-corrected spectra where the S(1) H$_2$ line should appear if present (bottom panel). None of the observed sources showed evidence for H$_2$ emission close to 17.035 μm.

In the flux-calibrated spectra, we used two different methods to determine the standard deviation (σ) of the continuum flux. First, we calculated the standard deviation for wavelength ranges relatively unaffected by telluric absorption, and close to the wavelength of interest. Second, we estimated σ in regions of the spectra with comparable atmospheric transmission to the line of interest. The first method provided more conservative values of σ for all but one star, namely HD 98922; for this star, the line of interest should be detected at wavelengths corresponding to the strong telluric absorption line, and the atmospheric transmission played an important role. For our analysis, we kept the more conservative values, and used the σ values obtained with

1 http://www.eso.org/sci/facilities/paranal/instruments/visir/tools/
the first method for HD 250550, HD 259431, and HD 45677, and the value given by the second method for HD 98922. The 3σ upper limits on the integrated line fluxes were calculated by integrating over a Gaussian of full width at half maximum (FWHM) equal to a spectral resolution element (Δv ≳ 21 km s⁻¹), and an amplitude of about 3 × σP (flux), centered on the expected wavelength for the S(1) line (Fig. 1). The upper limits on integrated fluxes and intensities of the S(1) line derived for each star are tabulated in Table 2. These limits were typically a factor of 2 lower than the detection towards HD 97048 (Martin-Zaïdi et al. 2007). The intensities were calculated by dividing the integrated fluxes by the solid angle of the slit of about 0.75″ width with a spatial resolution element of about 0.427″.

From the upper limits on integrated intensities and by assuming that the emitting H₂ is optically thin at LTE, we estimated the total column densities of H₂ for details on the method, see van Dishoeck (1992) as a function of adopted temperatures (150, 300, 1000 K). Even though the FUSE data indicated the presence of a gas component with T ≳ 100 K for our target stars, we measured 150 K to be the lowest temperature of the gas, which can emit in the H₂ S(1) line. For temperatures below 150 K, the S(0) line at 28 μm (not observable from the ground) provides more reliable constraints on the optically thin gas properties than the S(1) line.

Under the same assumptions and assuming a homogeneous medium, the mass of warm H₂ is given by:

\[ M_{\text{warm gas}} = f \times 1.76 \times 10^{-20} \frac{F_{\text{ul,}} d^2}{(hc/4\pi I) A_{\text{ul,}} x_\text{q}(T)} M_\odot, \]

where \( F_{\text{ul,}} \) is the line flux, \( d \) is the distance in pc to the star, \( \lambda \) is the wavelength of the transition \( u - l \), \( A_{\text{ul,}} \) is the spontaneous transition probability, \( x_\text{q}(T) \) is the fractional population of the level \( u \) at the temperature \( T \) in LTE, and \( f \) is the conversion factor required for deriving the total gas mass from the \( H_2-\text{ortho} \) or \( H_2-\text{para} \) mass, assuming that ortho/para ratio is controlled by the gas temperature (from Eq. (1) in Takahashi 2001). Our results are presented in Table 2. The upper limits on the masses are calculated by assuming the distances quoted in Table 1. For HD 98922, we used the lower limit on the distance and its mass scales with the distance as \( d^2 \).

### 5. Discussion

We observed five HBe stars with the high resolution spectroscopic mode of VISIR to search for \( H_2 \) pure rotational S(1) emission at 17.0348 μm. As probed by previous FUSE observations, the \( C_\text{S} \) environments of these stars provide evidence of large reservoirs (\( N(\text{H}_2) \sim 10^{21} \text{ cm}^{-2} \)) of cold \( H_2 \) (\( T \sim 100 \text{ K} \)), and also evidence for the presence of warm/hot excited \( H_2 \) (\( T \geq 500 \text{ K} \)).

The \( H_2 \) observed by FUSE, probably corresponds to the remnants of the molecular cloud in which the stars were formed and the observed H₂ FUV lines do not originate in a CS disk. Martin-Zaïdi et al. (2008) modeled the excitation conditions of \( H_2 \) and the FUSE spectra of HBes using the Maedon PDR Code and showed that the observed gas was located in relatively diffuse regions (10−3000 cm⁻³) at significant distances from the central stars (0.03−1.5 pc).

None of the four targets with spectra of sufficiently high S/N showed any evidence for \( H_2 \) emission. From the 3σ upper limits to the emission line flux, we calculated upper limits on the column density and mass of \( H_2 \) for each star. We found that the column densities should be lower than \( 10^{21} \text{ cm}^{-2} \) at 150 K, and lower than \( 10^{22} \text{ cm}^{-2} \) at 1000 K, which does not contradict the column densities derived from the FUSE observations. Upper limits to the masses of warm gas have been estimated to be in the range from \( 10^{-4} \) to \( 6 M_{\text{Jup}} \) (1 M₉₃ ⋅ 3 M₉₃), assuming LTE excitation, and depending on the adopted temperature.

It should be pointed out that mid-IR H₂ lines only probe warm gas located in the surface layers of the observed media because of the opacity of the interior layers when dust is present. The surface layers of any potential disks surrounding our target stars do not therefore contain sufficient warm gas to enable it to be detected in emission at mid-IR wavelengths. Following the calculations of Carmona et al. (2008), the \( H_2 \) mid-IR lines produced by a gas-rich disk with \( T_{\text{gas}} \sim T_{\text{dust}} \) should not be observable with existing instruments. As shown by Bittner et al. (2007) and Martin-Zaïdi et al. (2007) the warm \( H_2 \) can be detected in the CS disk of a Herbig star, but to explain the detection, particular conditions have to be assumed for the gas and dust, such as \( T_{\text{gas}} > T_{\text{dust}} \), which may be created by gas heating by X-rays or UV photons. Our non-detections therefore imply either that the gas and dust in any potential disks are well mixed and have almost equal temperatures, or that these disks are simply not present at all.

### Acknowledgements

This work is based on observations obtained at ESO/VLT (Paranal) with VISIR, program number 076.C-0299. C.M.Z. warmly thank M. Deleuil and J.-C. Bouret for their help in preparing the observations. We thank X. Delfosse (LAOG) and the anonymous referee for their fruitful comments about the noise estimates. CMZ was supported by a CNES fellowship.

* Masses of \( H_2 \) are calculated assuming the distances quoted in Table 1 (see text). For HD 98922, the lower limit on the distance is used and the mass scales with the distance as \( d^2 \).
