We present the redshift results from a Very Large Telescope program aimed at optimizing the legacy value of the Swift mission: to characterize a homogeneous, X-ray selected, sample of 69 GRB host galaxies. 19 new redshifts have been secured, resulting in a 83% (57/69) redshift completion, making the survey the most comprehensive in terms of redshift completeness of any sample to the full Swift depth, available to date. We present the cumulative redshift distribution and derive a conservative, yet small, associated uncertainty. We constrain the fraction of Swift GRBs at high redshift to a maximum of 10% (5%) for $z > 6$ ($z > 7$). The mean redshift of the host sample is assessed to be $\langle z \rangle \gtrsim 2.2$. Using this more complete sample, we confirm previous findings that the GRB rate at high redshift ($z \gtrsim 3$) appears to be in excess of predictions based on assumptions that it should follow conventional determinations of the star formation history of the universe, combined with an estimate of its likely metallicity dependence. This suggests that either star formation at high redshifts has been significantly underestimated, for example due to a dominant contribution from faint, undetected galaxies, or that GRB production is enhanced in the conditions of early star formation, beyond those usually ascribed to lower metallicity.

PRESENTED AT

"Huntsville in Nashville" Gamma-Ray Burst Symposium
Nashville, USA, April 14–18, 2013
1 Introduction

We have secured GRB host galaxy information for a homogeneous sample of 69 *Swift* GRBs with a large program at the Very Large Telescope (VLT) [1]. The sample has been carefully selected and obeys strict and well-defined criteria. To optimize the survey, we focused on systems with the best observability, which also have the best available information. The main results of The Optically Unbiased GRB Host (TOUGH) survey is presented in [2, 3, 4, 5], including fundamental properties of the hosts, Lyα emission and new redshifts.

Here we present the TOUGH campaign for missing redshifts via VLT/FORS [3] and VLT/X-shooter [5]. We attempted spectroscopic observations of most TOUGH host candidates with $R \lesssim 25.5$ mag that did not have a reported reliable redshift. In a nutshell, our approach is to reach as high a redshift completion as possible and not rely on pseudo-redshifts, e.g. [6]. We believe that examining the entire iceberg is significantly more successful than using the tip of it for extrapolation.

2 Redshift Measurements and Constraints

We have obtained 19 new host redshifts; Fig.1 shows the cumulative redshift distribution of the 57 TOUGH bursts with a measured redshift. Also plotted is a conservative systematic error band (hatched region) containing information for all the 69 TOUGH bursts. The shaded region represents the likely statistical ($1\sigma$ standard error of the sample) uncertainty of the measured redshift distribution under the assumption that it is a true random sample of the overall population. The sampling error and the conservative systematic error region are shown separately to clearly illustrate that incompleteness dominates the sample, and more is gained by reducing the systematics rather than increasing the sample size. Using both error regions we can set a conservative limit on the maximum number of *Swift* bursts at $z > 6$ ($z > 7$): 10% (5%).

The average (median) redshift of the 57 TOUGH bursts is $\langle z \rangle = 2.21$ ($\tilde{z} = 2.06$), significantly lower than the early *Swift* results indicated [7]. This difference may simply reflect the comparatively small samples analyzed in that paper, but could also be due to an increased success in measuring redshifts $z < 2$ using weaker absorption lines in afterglow spectra, and via host galaxies. Indeed, the average of the 19 new redshifts is $\langle z \rangle = 1.83$. The mean redshift of the whole TOUGH sample could be as low as $\langle z \rangle \sim 1.9$ (upper boundary of the hatched region) although it is unlikely that the majority of bursts with unknown redshifts would be located at very small distances. In fact, it is more probable that $\langle z \rangle \gtrsim 2.2$ since we have only targeted the brightest galaxies in the sample ($R \lesssim 25.5$ mag) for spectroscopic follow-up.
Figure 1: **Thick solid curve**: the cumulative fraction of GRBs as a function of redshift for the 57 Swift bursts in the TOUGH sample with a measured redshift ($\langle z \rangle = 2.21$). **Hatched region**: this is a conservative error region showing the systematic error on the thick solid curve. **Shaded region**: statistical region showing the 1σ sampling error band around the thick solid curve. **Dotted curve**: the expected redshift distribution for Swift observable long GRBs using the SFR1 history parameterization, i.e. the canonical SFR history discussed in [9] (see the main text). **Dashed curve**: the same redshift distribution for the SFR2 history parameterization, i.e. a model where the SFR history remains constant beyond $z \sim 3$ [13] (see the main text). Updated from [3].
3 Modelling

Illustrative model fits are presented in [3] and described in detail there. We assume that the GRB rate follows the star-formation rate (SFR) history, and consider two different SFR history parameterizations which we label as follows. *SFR1* is an update [8] of the SFR history models of [9] to include data from [10, 11], combined with a low-metallicity modification following the prescription of [12]. *SFR2* is model A from [13] which represents a SFR history which remains constant beyond \( z \sim 3 \). It may, for example, be considered a more extreme low-metallicity correction to the cosmic SFR. Or it may represent a correction [14, 15] to the high-redshift SFR as estimated from flux-limited surveys by the integration of galaxy luminosity functions (LFs) thus obtained. This would be due to a large amount of hidden star formation in faint, low-mass, and high specific SFR galaxies of the type that GRBs tend to be associated with at lower redshift.

Modeling is performed in the standard manner [16] to produce \( \log N - \log L \) number count distributions for various parameters of the LF, which are then fit by \( \chi^2 \) minimization to the observed \( \log N - \log L \) distribution of all *Swift* bursts with peak photon flux \( > 1 \text{ cm}^{-2}\text{s}^{-1} \). We emphasize that the redshift distribution is not part of this fitting procedure, but is always purely a result. In Fig. 1 we plot the redshift distributions from our best fitting models in comparison to the TOUGH redshift data.

At face value, these results seem to imply that GRBs follow a cosmic SFR history that is significantly enhanced at high redshift compared to estimates from flux-limited surveys. Given what is known about GRB hosts, it is entirely feasible that GRBs trace star formation at high redshift that would be undetectable by other means. It is of course also possible that the simple low-metallicity enhanced SFR parameterization used in the *SFR1* model is inadequate, or that the LF could have a more complex form and/or evolve with redshift. It should also be noted that [18] find that there is no strong preference for a metallicity cut.

4 Discussion

It is possible that star formation at high redshifts has been significantly underestimated. Even at \( z \sim 2 \) it appears that the galaxy LF has a substantially steeper faint-end slope than locally [17], while recent LF studies in the Hubble Ultra-Deep Field have concluded that at \( z \gtrsim 7 \) so-far undetected galaxies are likely to completely dominate the total star formation activity [19, 20]. Alternatively, it could be that GRB production is substantially enhanced in the conditions of early star formation, beyond the metallicity-dependent rate correction already applied. In the long run, large complete samples of GRB redshifts should shed light on whether the GRB rate is proportional to SFR or whether other effects play an important role.
We have now reached a point in GRB research where a single burst rarely elucidates and illuminates our general understanding of the field. It is important to focus on well-defined samples and population studies, where systematics and biases can be minimized. *Swift* has made it possible to build such a sample and thanks to new available instrumentation, such as the VLT/X-shooter [21], we can continue to follow this track into the future.

ACKNOWLEDGEMENTS

P.J. acknowledges support by a Project Grant from the Icelandic Research Fund. The Dark Cosmology Centre is funded by the Danish National Research Foundation. This work has made use of the University of Hertfordshire Science and Technology Research Institute high-performance computing facility.
