Fabry-Perot cavities, optical resonators, are commonly utilized for high-precision frequency and distance measurements [1]. Currently, kilometer-scale Fabry-Perot cavities with suspended mirrors are being employed in efforts to detect cosmic gravitational waves [2-3]. This application has stimulated renewed interest in cavities and motivated efforts to model the dynamics of such cavities on the computer [4, 5, 6, 7]. Recently, several studies addressed the process of lock acquisition in which the cavity mirrors move through the resonance positions [8, 9, 10]. In this process, the Doppler effect due to the mirror motions impedes constructive interference of light in the cavity giving rise to complex field dynamics. In contrast, Fabry-Perot cavities held in the state of resonance have usually been treated as essentially static. In this letter, we show that resonant cavities also have complex field dynamics and we derive the condition for dynamic resonance. Our analysis is developed for the very long Fabry-Perot cavities of gravitational wave detectors, but the results are general and apply to any cavities, especially when the frequencies of interest are close to the cavity free spectral range.

We consider a Fabry-Perot cavity with a laser field incident from one side as shown in Fig. 1. Variations in the cavity length are due to the mirror displacements $x_a(t)$ and $x_b(t)$ which are measured with respect to reference planes $a$ and $b$. The nominal light transit time and the free spectral range (FSR) of the cavity are defined by

$$T = L/c, \quad \omega_{fsr} = \pi/T. \quad (1)$$

The field incident upon the cavity and the field circulating in the cavity are described by plane waves with nominal frequency $\omega$ and wavenumber $k$ ($k = \omega/c$). Variations in the laser frequency are denoted by $\delta \omega(t)$. We assume that the mirror displacements are much less than the nominal cavity length and that the deviations of the laser frequency are much less than the nominal frequency.

At any given place the electric field $E$ in the cavity oscillates at a very high frequency: $E(t) \propto \exp(i\omega t)$. For simplicity, we suppress the fast-oscillating factor and define the slowly-varying field as $E(t) = \mathcal{E}(t) \exp(-i\omega t)$. To properly account for the phases of the propagating fields, their complex amplitudes are defined at fixed locations, reference planes $a_1$ and $a_2$, as shown in Fig. 1. (The small offset $\epsilon$ is introduced for convenience and can be set to zero at the end of calculations.)

The equations for fields in the cavity can be obtained by tracing a wavefront during its complete round-trip in the cavity (starting from the reference plane $a_2$). The propagation delays $\tau_1$ and $\tau_2$ depend on the mirror positions and are given by

$$c \tau_1 = L - \epsilon + x_b(t - \tau_1), \quad \tau_2 = \epsilon - x_a(t - \tau_2). \quad (2)$$

Then the fields in the cavity satisfy the equations:

$$E'(t) = -r_b E(t - 2\tau_1) e^{-2i\omega \tau_1}, \quad (4)$$

$$E(t) = -r_a E'(t - 2\tau_2) e^{-2i\omega \tau_2} + t_a E_{in}(t - 2\epsilon/c), \quad (5)$$

where $r_a$ and $r_b$ are the mirror reflectivities, and $t_a$ is the transmissivity of the front mirror.

Because the field amplitudes $E$ and $E'$ do not change significantly over times of order $x_{a,b}/c$, the small variations in these amplitudes during the changes in propagation times due to mirror displacements can be neglected. Furthermore, the reference planes $a$ and $b$ can be chosen so that the nominal length of the Fabry-Perot cavity becomes an integer multiple of the laser wavelength, making

![FIG. 1: Mirror positions and fields in a Fabry-Perot cavity.](image-url)
exp(−2ikL) = 1. Finally, the offset ε can be set to zero, and Eqs. (3) and (4) can be combined yielding one equation for the cavity field
\[ E(t) = t_a E_{in}(t) + r_a r_b E(t - 2T) \exp[-2i k \delta L(t)]. \] (6)

Here \( \delta L(t) \) is the variation in the cavity length “seen” by the light circulating in the cavity,
\[ \delta L(t) = x_b(t - T) - x_a(t). \] (7)

Note that the time delay appears in the coordinate of the end mirror, but not the front mirror. This is simply a consequence of our placement of the laser source; the light that enters the cavity reflects from the end mirror first and then the front mirror. For \( \delta L = 0 \), Laplace transformation of both sides of Eq. (6) yields the basic cavity response function
\[ H(s) \equiv \frac{\tilde{E}(s)}{\tilde{E}_{in}(s)} = \frac{t_a}{1 - r_a r_b e^{-2sT}}, \] (8)

where tildes denote Laplace transforms.

The static solution of Eq. (3) is found by considering a cavity with fixed length (\( \delta L = \text{const} \)) and an input laser field with fixed amplitude and frequency (\( A, \delta \omega = \text{const} \)). In this case the input laser field and the cavity field are given by
\[ E_{in}(t) = A e^{i \delta \omega t}, \] (9)
\[ E(t) = E_0 e^{i \delta \omega t}, \] (10)

where \( E_0 \) is the amplitude of the cavity field,
\[ E_0 = \frac{t_a A}{1 - r_a r_b \exp[-2i(T \delta \omega + k \delta L)]}. \] (11)

The cavity field is maximized when the length and the laser frequency are adjusted so that
\[ \frac{\delta \omega}{\omega} = - \frac{\delta L}{L}. \] (12)

This is the well-known static resonance condition. The maximum amplitude of the cavity field is given by
\[ \bar{E} = \frac{t_a A}{1 - r_a r_b}. \] (13)

Light can also resonate in a Fabry-Perot cavity when its length and the laser frequency are changing. For a fixed amplitude and variable phase, the input laser field can be written as
\[ E_{in}(t) = A e^{i \phi(t)}, \] (14)
where \( \phi(t) \) is the phase due to frequency variations,
\[ \phi(t) = \int_0^t \delta \omega(t') dt'. \] (15)

Then the steady-state solution of Eq. (1) is
\[ E(t) = \bar{E} e^{i \phi(t)}, \] (16)

where the amplitude \( \bar{E} \) is given by Eq. (13) and the phase satisfies the condition
\[ \phi(t) - \phi(t - 2T) = -2k \delta L(t). \] (17)

Thus resonance occurs when the phase of the input laser field is corrected to compensate for the changes in the cavity length due to the mirror motions. The associated laser frequency correction is equal to the Doppler shift caused by reflection from the moving mirrors
\[ \delta \omega(t) - \delta \omega(t - 2T) = -2 \frac{v(t)}{c} \omega, \] (18)

where \( v(t) \) is the relative mirror velocity (\( v = \frac{d \delta L}{dt} \)). The equivalent formula in the Laplace domain is
\[ C(s) \frac{\bar{E}(s)}{\omega} = -\frac{\tilde{L}(s)}{L}, \] (19)

where \( C(s) \) is the normalized frequency-to-length transfer function which is given by
\[ C(s) = \frac{1 - e^{-2sT}}{2sT}. \] (20)

Eq. (19) is the condition for dynamic resonance. It must be satisfied in order for light to resonate in the cavity when the cavity length and the laser frequency are changing.

The transfer function \( C(s) \) has zeros at multiples of the cavity free spectral range,
\[ z_n = i \omega \text{fsr} n, \] (21)

where \( n \) is integer, and therefore can be written as the infinite product,
\[ C(s) = e^{-sT} \prod_{n=1}^{\infty} \left(1 - \frac{s^2}{z_n^2}\right), \] (22)

which is useful for control system design[18].

To maintain resonance, changes in the cavity length must be compensated by changes in the laser frequency according to Eq. (19). If the frequency of such changes is much less than the cavity free spectral range, \( C(s) \approx 1 \) and Eq. (19) reduces to the quasi-static approximation,
\[ \frac{\delta \bar{E}(s)}{\omega} \approx -\frac{\tilde{L}(s)}{L}. \] (23)

At frequencies above the cavity free spectral range, \( C(s) \propto 1/s \) and increasingly larger laser frequency changes are required to compensate for cavity length variations. Moreover, at multiples of the FSR, \( C(s) = 0 \) and no frequency-to-length compensation is possible.
In practice, Fabry-Perot cavities always deviate from resonance, and a negative-feedback control system is employed to reduce the deviations. For small deviations from resonance, the cavity field can be described as

\[ E(t) = [\bar{E} + \delta E(t)]e^{i\phi(t)}, \]

where \( \bar{E} \) is the maximum field given by Eq. (13), and \( \delta E \) is a small perturbation \((|\delta E| \ll |\bar{E}|)\). Substituting this equation into Eq. (6), we see that the perturbation evolves in time according to

\[ \delta E(t) - r_a r_b \delta E(t - 2T) = -ir_a r_b \bar{E} [\phi(t) - \phi(t - 2T) + 2k \delta L(t)]. \]

This equation is easily solved in the Laplace domain, yielding

\[ \delta \tilde{E}(s) = -ir_a r_b \bar{E} \left( \frac{1 - e^{-2sT}}{1 - r_a r_b e^{-2sT}} \right) \tilde{\phi}(s) + 2k \delta \tilde{L}(s). \]

Deviations of the cavity field from its maximum value can be measured by the Pound-Drever-Hall (PDH) error signal which is widely utilized for feedback control of Fabry-Perot cavities [13]. The PDH signal is obtained by coherent detection of phase-modulated light reflected by the cavity. With the appropriate choice of the demodulation phase, the PDH signal is proportional to the imaginary part of the cavity field (Eq. (26)) and therefore can be written as

\[ \delta \tilde{V}(s) \propto H(s) \left[ \frac{\delta \tilde{L}(s)}{L} + C(s) \frac{\delta \tilde{\omega}(s)}{\omega} \right], \]

where \( H(s) \) is given by Eq. (8). In the presence of length and frequency variations, feedback control will drive the error signal toward the null point, \( \delta \tilde{V} = 0 \), thus maintaining dynamic resonance according to Eq. (14).

The response of the PDH signal to either length or laser frequency deviations can be found from Eq. (27). The normalized length-to-signal transfer function is given by

\[ H_L(s) = \frac{H(s)}{H(0)} = \frac{1 - r_a r_b}{1 - r_a r_b e^{-2sT}}. \]

A Bode plot (magnitude and phase) of \( H_L \) is shown in Fig. 2 for the LIGO Fabry-Perot cavities with \( L = 4 \) km, \( r_a = 0.985 \), and \( r_b = 1 \). The magnitude of the transfer function,

\[ |H_L(i\Omega)| = \frac{1}{\sqrt{1 + F \sin^2 \Omega T}} \]

is the square-root of the well-known Airy function with the coefficient of finesse \( F = 4r_a r_b/(1 - r_a r_b)^2 \). (In optics, the Airy function describes the intensity profile of a Fabry-Perot cavity [15].)

The transfer function \( H_L \) has an infinite number of poles:

\[ p_n = -\frac{1}{\tau} + i\omega_{\text{fsr}} n, \]

where \( n \) is integer, and \( \tau \) is the storage time of the cavity,

\[ \tau = \frac{2T}{\ln(r_a r_b)}. \]

Therefore, \( H_L \) can be written as the infinite product,

\[ H_L(s) = e^{sT} \prod_{n=-\infty}^{\infty} \frac{p_n}{p_n - s}, \]

which can be truncated to a finite number of terms for use in control system design.

FIG. 2: Bode plot of \( H_L(i\Omega) \) for the LIGO 4-km Fabry-Perot cavities. The peaks occur at multiples of the FSR (37.5 kHz) and their half-width (91 Hz) is equal to the inverse of the cavity storage time.

FIG. 3: Bode plot of \( H_L(i\Omega) \). The sharp features are due to the zero-pole pairs at multiples of the FSR.
The response of a Fabry-Perot cavity to laser frequency variations is very different from its response to length variations. The normalized frequency-to-signal transfer function is given by

\[ H_L(s) = C(s)H_L(s), \]  

or, more explicitly as

\[ H_\omega(s) = \left( \frac{1-e^{-2\pi T}}{2sT} \right) \left( \frac{1-r_aT_b}{1-r_aT_b e^{-2\pi T}} \right). \]  

A Bode plot of \( H_\omega \), calculated for the same parameters as for \( H_L \), is shown in Fig. 3. The transfer function \( H_\omega \) has zeros given by Eq. (21) with \( n \neq 0 \), and poles given by Eq. (20). The poles and zeros come in pairs except for the lowest order pole, \( p_0 \), which does not have a matching zero. Therefore, \( H_\omega \) can be written as the infinite product,

\[ H_\omega(s) = \frac{p_0}{p_0-s} \prod_{n=\infty}^{\prime} \left( \frac{1-s/z_n}{1-s/p_n} \right), \]  

where the prime indicates that \( n = 0 \) term is omitted from the product.

The zeros in the transfer function indicate that the cavity does not respond (\( \delta E = 0 \)) to laser frequency deviations if these deviations occur at multiples of the cavity FSR. In this case, the amplitude of the circulating field is constant while the phase of the circulating field is changing with the phase of the input laser field.

In summary, we have shown that resonance can be maintained in a Fabry-Perot cavity even when the cavity length and laser frequency are changing. In this dynamic resonance state, changes in the laser frequency and changes in the cavity length play very different roles (Eq. (35)) in contrast to the quasi-static resonance state where they appear equally (Eq. (23)). Maintenance of dynamic resonance requires that the frequency-to-length transfer function, \( C(s) \), be taken into account when compensating for length variations by frequency changes and vice versa. Compensation for length variations by frequency changes becomes increasingly more difficult at frequencies above the FSR, and impossible at multiples of the FSR.

As the density of the mirrors, the response of the PDH error signal to laser frequency variations decreases as \( 1/\Omega \) for \( \Omega \gg \tau^{-1} \) and becomes strongly suppressed at frequencies equal to multiples of the cavity FSR. In contrast, the response to length variations is a periodic function of frequency as shown in Fig. 2. For \( \Omega \gg \tau^{-1} \), it also decreases as \( 1/\Omega \) but only to the level of \( (1+F)^{-1/2} \) and then returns to its maximum value. Thus, at multiples of the FSR, the sensitivity to length variations is maximum while the sensitivity to frequency variations is minimum.

Both these features suggest searches for gravitational waves at frequencies near multiples of the FSR. However, because gravitational waves interact with the light as well as the mirrors, the response of an optimally-oriented interferometer is equivalent to \( H_\omega(s) \) and not to \( H_L(s) \). This, an optimally-oriented interferometer does not respond to gravitational wave at multiples of the FSR. However, for other orientations gravitational waves can be detected with enhanced sensitivity at multiples of the cavity FSR.

We thank Robert Coldwell, Guido Mueller and David Shoemaker for comments on the paper. This research was supported by the National Science Foundation under grants PHY-9210038 and PHY-0070854.
