Advances:

- Recent evidence highlights the importance of chloroplast-generated ROS production in response to pathogen infection
- TRXs may confer selective redox signaling through chemical features and electrostatic complementarity
- New proteomic tools are beginning to uncover selective ROS/RNS signaling dynamics and the plant immune ‘redoxome’
- Recent studies are advancing our understanding of how pathogens manipulate host redox systems

Outstanding questions:

- How are redox signaling pathways rendered specific and reversible?
- Can newly emerging proteomic tools uncover the full extent of TRX redundancy and specificity in the plant immune response?
- To what extent do pathogens manipulate plant TRX systems?
- How do additional environmental stresses affect redox signaling networks of the plant immune response?
Plants have evolved extensive signaling networks to regulate physiological responses to environmental stresses, both biotic and abiotic. Customary to many of these networks is the use of reactive oxygen and nitrogen species (ROS and RNS, respectively) as signaling tools. Signal-induced accumulation of ROS and RNS perturbs the homeostatic ‘redox state’ of the cell (Spoel and Loake, 2011; Torres et al., 2006), which can result in detrimental protein oxidation and severe cellular damage. Therefore, it was widely assumed that ROS/RNS were toxic by-products of metabolism, whereas ROS/RNS scavenging antioxidant systems were seen as solely responsible for keeping undesirable ROS/RNS at low levels (Noctor, 2006). However, it is now established that ROS/RNS and antioxidant enzymes are vital signaling tools for intra- and intercellular signaling and communication. Compared to other kingdoms, redox-related enzymes are particularly prevalent in plant genomes (Birben et al., 2012; Geigenberger et al., 2017; Meyer et al., 2009), suggesting plants have evolved numerous mechanisms to exploit ROS/RNS to their benefit. Indeed, ROS/RNS predominantly signal by oxidising proteins. Metal chelating and aromatic amino acids are subject to irreversible oxidation, whereas methionine and relatively rare reactive cysteine (Cys) residues are reversibly oxidised in signaling proteins. ROS/RNS production and associated regulation by protein oxidation and particularly Cys oxidation are key aspects of plant immune responses. Extracellular perception of pathogen-associated molecular patterns (PAMPs) by pattern recognition receptors (PRRs) as well as intracellular detection of pathogen effectors by nucleotide-binding leucine-rich repeat (NLR) immune receptors result in production of ROS/RNS. But how these ROS/RNS selectively modify Cys residues to regulate specific signaling pathways remains largely unknown. Selective signaling is likely established by the diversity in ROS/RNS produced, their dynamic cellular location, ability to generate diverse oxidative Cys modifications, and the cellular distribution of different antioxidant systems. Here we discuss how redox signaling may be rendered selective and reversible in plant immune responses. Moreover, we explore how pathogens hijack host redox signaling and utilise their own antioxidant systems to promote virulence.
SELECTIVE ROS/RNS PRODUCTION IN RESPONSE TO PATHOGEN DETECTION

One of the earliest responses upon pathogen detection is the ‘oxidative burst’, resulting in the rapid generation and accumulation of ROS/RNS. Diverse reactive species may be produced, including singlet oxygen (\(^1\text{O}_2\)), superoxide (O\(_2^−\)), hydrogen peroxide (H\(_2\text{O}_2\)), hydroxyl radicals (\(\cdot\text{OH}\)), nitric oxide (NO), and other NO derivatives. These molecules have distinct reactivities, different stabilities, and are produced by different cellular compartments, thereby generating the potential for selective signaling. The apoplast and the chloroplast are the main sites of ROS production upon pathogen detection (Figure 1). ROS/RNS can cause direct harm to the invading pathogen by triggering localised programmed cell death to prevent the spread of infection, callose deposition, and cross-linking of glycoproteins in cell walls (Daudi et al., 2012; O’Brien et al., 2012a; Torres et al., 2006). Alternatively, ROS/RNS act in cellular signaling or as long distance signaling molecules via interaction with immune hormones such as salicylic acid (SA) (Fichman and Mittler, 2020; Miller et al., 2009; Wang et al., 2014).

Apoplastic ROS Production

Pathogen-induced apoplastic ROS is largely produced by transmembrane localised NADPH oxidases, known as Respiratory Burst Oxidase Homologs (RBOHs). RBOHs transfer electrons from intracellular NADPH across the plasma membrane where they are coupled to molecular oxygen in the apoplast to produce O\(_2^−\) (Figure 1) (Suzuki et al., 2011). O\(_2^−\) is short lived and rapidly converted to H\(_2\text{O}_2\), either spontaneously or by superoxide dismutase (SOD), and enters the cell through plasma membrane channels. The Arabidopsis thaliana genome contains 10 RBOH genes, with RBOHD and RBOHF being the main producers of ROS upon PAMP recognition and both required for programmed cell death initiated after pathogen effector detection (Torres et al., 2002). RBOHs have been shown to have overlapping functions, but there is emerging evidence that they may also have more specific roles depending on the type of pathogen encountered. Indeed, RBOHD and RBOHF show differential spatio-temporal expression levels and patterns in response to PAMPs,
(hemi)biotrophic pathogens, and necrotrophic pathogens (Morales et al., 2016). A further clue that RBOH-mediated ROS production is finely regulated comes from its complex regulation by various post-translational modifications, including phosphorylation. Both RBOHD and RBOHF are differentially phosphorylated at multiple residues by at least half a dozen different types of kinases that modulate their activity and stability (Han et al., 2019; Kadota et al., 2015; Kimura et al., 2020, 2017; Lee et al., 2020). These multiple post-translational control points suggest that ROS production and signaling can be selectively fine-tuned based on the type of pathogen encountered.

In addition to NADPH oxidases, apoplastic ROS can also be induced by peroxidases. The Class III peroxidases PRX33 and PRX34 are important in the activation of PAMP-triggered immunity, as knockdown mutants in Arabidopsis cell cultures show much reduced H$_2$O$_2$ levels in response to PAMP treatments and a decrease in expression of PAMP-induced defence-related proteins (O’Brien et al., 2012b). The absence of functional PRX33 and PRX34 resulted in increased susceptibility to the bacterial leaf pathogen *Pseudomonas syringae*, highlighting their role in early pathogen responses (Daudi et al., 2012). Moreover, activity of ascorbate oxidase (AO) reduces apoplastic amounts of the antioxidant ascorbate, thereby generating an environment in which apoplastic ROS can be sustained (Foyer et al., 2019). How the ROS-related activities of RBOH, PRX, and OA enzymes are balanced remains unknown, but their interplay likely generates specific ROS signatures depending on the stress encountered.

**Pathogen-induced ROS Production by the Chloroplast**

Pathogen-induced apoplastic ROS production is well established and has been extensively reviewed in recent years (Kadota et al., 2015; Qi et al., 2017). However, the importance of organelles, particularly the chloroplast, in pathogen-induced ROS production and downstream immune signaling has only recently emerged. Chloroplasts are the source of both ROS and NO through respectively the electron transport chain and thylakoid-associated nitrite reductase or an NO-synthase-like enzyme (Figure 1) (Lu and Yao, 2018).
Indeed, PAMP perception leads to a second burst of ROS generated by the chloroplast that occurs after apoplastic ROS production (de Torres Zabala et al., 2015). Moreover, infection with a disabled *P. syringae* strain, deficient in delivering pathogen effectors into host cells, but not wild-type *P. syringae*, resulted in chloroplastic ROS production. As opposed to the wild-type, the disabled strain is largely non-infectious, suggesting that chloroplastic ROS may contribute to immunity. In accordance, it was also observed that inhibition of H$_2$O$_2$ production via photosystem II with 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU), abolished ROS production and promoted virulence of this disabled pathogen (de Torres Zabala et al., 2015). In contrast to this hemibiotroph, chloroplastic ROS production has been shown to facilitate infection by the necrotrophic fungal pathogen *Botrytis cinerea*. By targeting a cyanobacterial antioxidant, flavodoxin, to the chloroplast to lower ROS accumulation, a decrease in tissue damage and hyphal growth was observed (Rossi et al., 2017).

Because chloroplasts have important roles in regulating localised cell death and nuclear gene expression (Straus et al., 2010; Zurbriggen et al., 2009), it is likely that the chloroplast generated ROS signal is perceived throughout the cell. Using the genetically encoded biosensors Grx1-roGFP2 and roGFP2-Orp1 that respectively measure cellular glutathione redox potential and endogenous H$_2$O$_2$, it was indeed shown that methyl viologen-induced chloroplastic ROS generation led to rapid oxidation in the chloroplast and subsequently also in the cytosol and mitochondria (Ugalde et al., 2020). Thus, chloroplasts play a key role in orchestrating cellular responses to stress, including pathogen infection. This is perhaps best illustrated by the fact that upon pathogen infection, chloroplasts either congregate around the nucleus or send out dynamic extensions along microtubules called stromules that physically connect to the nucleus (Caplan et al., 2015; Kumar et al., 2018). Interestingly, exogenous application of H$_2$O$_2$ but not of NO or O$_2^-$, mimicked stromule formation induced by pathogen infection, indicating that this process is coordinated by specific ROS. Chloroplast rearrangements towards the nucleus may be a general response to infection, as Ding et al. (2019) observed this process after treatment of *Nicotiana*
benthamiana with bacteria, viruses, bacterial elicitors, or exogenous H₂O₂. Interestingly, treatment with the NADPH-oxidase inhibitor diphenyleneiodonium (DPI), or the ROS scavengers dimethylthiourea (DMTU) and Tiron resulted in a drastic reduction in the percentage of nuclei surrounded by chloroplasts (Ding et al., 2019). These findings suggest that pathogen-induced H₂O₂ produced in the apoplast by NADPH oxidases signals to chloroplasts prior to the chloroplastic ROS burst.

Pathogen-Induced NO and NO Derivatives

In animals, NO is one of the main RNS and is synthesized by dedicated nitric oxide synthetases (NOS). NO is formed by the NADPH-dependent oxidation of L-arginine to NO and citrulline. However, a bona fide NOS has not yet been identified in higher plants. Instead, in plants NO is synthesised through alternative routes that have been reviewed in detail elsewhere (Astier et al., 2018). One of the main sources of NO during the immune response is via nitrate reductases (NRs). The NR-deficient mutant nia1nia2 in Arabidopsis provided insight into the importance of NO in response to pathogen infection. Lower levels of endogenous NO in nia1nia2 mutants have been linked to regulation of oligogalacturonide-triggered immunity, elicitor-triggered immunity, and resistance to both the necrotrophic fungus B. cinerea and cucumber mosaic virus (CMV) (Jian et al., 2015; Rasul et al., 2012). In addition, NO feedback regulates the nitrogen assimilation pathway, thereby controlling its own production (Frungillo et al., 2014). Pathogen infection leads not only to the accumulation of free NO but also of the NO derivative S-nitrosoglutathione (GSNO). Both of these RNS play key roles in immunity as their respective overaccumulation in NO Overexpressing 1 (nox1) and GSNO Reductase 1 (gsnor1) mutants results in enhanced disease susceptibility (Feechan et al., 2005; Kneeshaw et al., 2014). While free NO• radicals are highly reactive and short-lived, GSNO is more stable and is thought to function as a cellular reservoir for NO bioactivity. The difference between these molecules in terms of molecular structure and mode of reactivity with Cys residues to form S-nitrosothiols (SNO) suggests that they could have distinct roles in cell signaling. In accordance, upon pathogen
infection, *gsnor1 nox1* double mutants displayed an increase in total cellular SNO upon pathogen perception and enhanced disease susceptibility compared to either of the single mutants (Yun et al., 2016). Moreover, overexpression of the GSNO scavenger enzyme *GSNOR1* rescued disease resistance in *gsnor1* but not in *nox1* mutants (Yun et al., 2016). These findings provide genetic evidence that RNS have distinct and selective signaling roles in plant immunity. The selective activities of ROS/RNS also cross-regulate each other to fine tune redox signaling (Box 1) (Lee et al., 2017).

**OXIDATIVE POST-TRANSLATIONAL MODIFICATIONS ORCHESTRATE IMMUNITY**

Pathogen-induced ROS/RNS alter the redox state of the cell by changing the oxidative status of small redox couples, including oxidised versus reduced glutathione (Spoel and Loake, 2011). Such redox changes can be sensed directly by signaling proteins of the immune system. For example, in unchallenged cells the immune transcription coactivator NPR1 (Non-Expressor of Pathogenesis Related Genes 1) resides in the cytoplasm as a disulphide-linked oligomer. Upon infection, an increasingly reduced cellular environment results in release of NPR1 monomer either by spontaneous reduction of disulfides or their cleavage by specific oxidoreductases (Mou et al., 2003; Tada et al., 2008). The NPR1 monomer then translocates to the nucleus where it orchestrates transcriptional reprogramming to prioritise immunity over other cellular processes (Kinkema et al., 2000; Wang et al., 2006). Signaling proteins like NPR1 may therefore be thought of as ‘redox sensors’ that sense and respond to the cellular redox environment.

ROS/RNS can also directly oxidise reactive Cys residues of signaling proteins (Waszczak et al., 2015). This results in oxidative post-translational modifications (oxPTMs) of diverse nature, including protein S-nitrosylation (–SNO), disulfides (–S–S), S-sulfhydration (–SSH), S-sulfenylation (–SOH), S-sulfination (–SO₂), and S-sulfonation (–SO₃). Except for the latter, all other oxPTMs are reversible either through small molecule- or enzymatic reduction. Reversible oxPTMs can also occur on methionine, another sulphur containing amino acid. Unlike Cys oxidation, which is pH-dependent and requires its thiols to be ionised
for oxidation to occur, methionine oxidation to methionine sulfoxide occurs over a broad pH range (Kim et al., 2014; Levine et al., 2000; Peskin and Winterbourn, 2001). Thus, oxPTMs ensure ROS/RNS signatures are translated into dynamic molecular processes. Recent work demonstrated that oxPTMs underpin perception of apoplastic H$_2$O$_2$ at the cell surface. A forward genetic screen based on imaging H$_2$O$_2$-induced calcium fluxes identified the plasma membrane-localised leucine-rich repeat receptor kinase HPCA1 (Hydrogen-Peroxide-induced Ca$^{2+}$ increases) (Wu et al., 2020). HPCA1 contains extracellular Cys residues that are oxidised upon exposure to H$_2$O$_2$, leading to its activation by autophosphorylation and downstream induction of calcium channels and stomatal closure. While currently known receptor-like kinases involved in pathogen perception did not respond to H$_2$O$_2$ in a similar manner (Wu et al., 2020), this mechanism of H$_2$O$_2$ perception appears to be conserved and could mediate H$_2$O$_2$ responses of yet unknown pathogen receptors.

Upon pathogen infection, intracellular ROS/RNS target numerous signaling proteins involved in a wide variety of cellular processes (Camejo et al., 2019; Waszczak et al., 2015). Thus, discovering ways to detect oxPTMs on a global proteomic scale is an important step forward towards uncovering how ROS/RNS regulate immune signaling proteins. Several key biochemical and proteomic methodologies have emerged over the past several years that have provided a global view of how pathogen-induced ROS/RNS may control cell signaling. Waszczak et al., (2014) developed a probe based on the C-terminal cysteine-rich domain of the yeast AP-1-like (YAP1C) transcription factor and were able to uncover the H$_2$O$_2$-dependent sulfenome (i.e. proteins that have a least one cysteine that has been modified by sulfenic acid). The authors detected a range of proteins in the first 10 minutes of H$_2$O$_2$-induced oxidative stress, including proteins involved in signal perception and transduction such as MAP kinases, as well as redox-related proteins such as thioredoxin-dependent peroxidase 1 and the Dehydroascorbate Reductase DHAR2 that is involved in the H$_2$O$_2$ scavenging pathway. This study provided one of the first deep insights into the array of redox-mediated signaling pathways and networks that can be uncovered with redox-specific proteomic tools. Further development of the YAP1C probe now allows it to be expressed in
vivo in specific cellular locations, including the chloroplast (De Smet et al., 2019). Such organelar proteomic approaches will be highly useful to understanding how the pathogen-induced apoplastic H$_2$O$_2$ burst is perceived intracellularly by proteins of the immune system. A drawback of the YAP1C probe is that it only identifies peptides that interact with the probe but not the identities of S-sulfenylated amino acids. A recent technological advancement now overcomes this limitation by using an anti-YAP1C-derived peptide antibody to purify YAP1C cross-linked target peptides, identifying S-sulfenylated cysteines in more than 1,000 proteins (Wei et al., 2020).

An emerging method for uncovering global oxPTMs, or the ‘redoxome’, is the use of chemical proteomics using Cys-reactive chemical probes, including activity-based protein profiling (ABPP) to detect changes in the activities of proteins on a proteome-wide scale. ABPP and other Cys-reactive proteomic methods commonly use probes that label the active site of enzymes, but are also suitable for labelling highly reactive Cys residues (Foyer et al., 2019; Morimoto and van der Hoorn, 2016). ABPP labelling is often irreversible and enables modified proteins or peptides to be purified and identified by mass spectrometry (Morimoto and van der Hoorn, 2016). Although successfully applied in plants, one of the limitations to ABPP was the lack of specificity it provided in terms of the type of oxPTM that is detected. However, more selective probes for specific oxPTMs are now emerging. Using an SNO-specific biotin probing method, Hu et al., (2015) identified over 900 endogenously S-nitrosylated proteins in the gsnor1-3 mutant that overaccumulates S-nitrosothiols. Moreover, using a benzothiazinedioxide (BTD) based probe in Arabidopsis cell cultures to identify S-sulfenylated proteins after H$_2$O$_2$ treatment, identified 1,537 -SOH sites, including specific sites of immune-associated MAPK4, which when mutated, inhibit its phosphorylative activity (Huang et al., 2019). Further development of probes has now enabled the identification of specific modified cysteines. Additional probes have been developed to enable the identification of free thiols, and other oxPTMs, including S-nitrosothiols (−SNO), sulfinic acids, and sulfhydrates, which can be applied to study plant immune signaling (Akter et al., 2018; Seneviratne et al., 2016; Zivanovic et al., 2019). However, specific probes have yet to
be described for sulfonic acids, while detection methods for disulfides and glutathionylates (-SG) are still primarily based on monocysteinic oxidoreductase substrate traps (Motohashi et al., 2001; Pérez-Pérez et al., 2017).

Recently, a label-free method uncovered cysteine reactivity across the proteome during the immune response. McConnell et al., (2019) studied the effects of pathogen effector-triggered immunity on Cys oxidation in wild-type plants and the top1top2 double mutant, which is deficient in the thimet oligopeptidases TOP1 and TOP2 that are involved in regulation of the oxidative burst and programmed cell death. This study demonstrated that TOP1/2 reinforced cellular oxidation dynamics upon immune activation and identified a wide repertoire of new oxPTMs involved in amongst others cell wall reinforcement and programmed cell death.

SELECTIVE AND REVERSIBLE OXIDATIVE SIGNALING

Considering the wide variety of oxPTMs and their ability to change protein function or activity, how are these modifications tightly controlled to enable cell signaling and to protect from protein hyperoxidation? Firstly, the chemistry of each ROS/RNS and the accessibility of their Cys targets play an important role. Protein conformation will selectively exclude access for some ROS/RNS but not others, while residues surrounding the oxPTM can stabilise or destabilise the oxidative group, thereby determining oxPTM turnover times. Secondly, the spatial and temporal production of ROS can selectively expose Cys residues to ROS/RNS. As described above for the plant immune system, the activities of enzymes such as NADPH oxidases are indeed tightly controlled by numerous post-translational modifications to ensure temporal production. Thirdly, cellular scavenging or antioxidant systems also determine the spatio-temporal effects of ROS/RNS on Cys residues. A recent study demonstrated that the glutathione antioxidant system determines the cytosolic effects of the apoplastic ROS burst induced by perception of pathogen patterns. In the absence of cytosolic glutathione reductase (GR1), cytosolic H$_2$O$_2$ levels increased earlier and were of higher amplitude,
indicating that in wild-type plants (reduced) glutathione effectively scavenged H\(_2\)O\(_2\) (Nietzel et al., 2019), thereby likely defining the spatiotemporal dynamics of ROS-mediated oxPTMs. In addition, ROS scavenging enzymes such as catalase and peroxidase enzymes, including ascorbate peroxidase (APX), peroxiredoxins (PRX), and glutathione peroxidases (GPX), have been shown to play roles in the immune response (Figure 1) (Choi et al., 2007; Daudi et al., 2012; Survila et al., 2016; Yuan et al., 2017). Silencing of the thylakoid-localised H\(_2\)O\(_2\) scavenging enzyme tAPX resulted in the activation of defence-related genes, including ICS2 which is responsible for SA biosynthesis and downstream expression of Pathogenesis-Related (PR) genes (Maruta et al., 2012). Additionally, the catalase CAT2 plays a role in hormonal immune signaling. Yuan et al. (2017) reported that CAT2 may function as an SA receptor, whereby SA inhibited its H\(_2\)O\(_2\) scavenging activity. Decreased activity of SA-bound CAT2 and associated increases in H\(_2\)O\(_2\) levels inhibited auxin and jasmonic acid biosynthesis enzymes, thereby alleviating the negative effects of these hormones on SA-mediated resistance to biotrophic pathogens. Thus, ROS scavenging enzymes may represent one of the missing links between hormone and ROS signaling, and have the potential to selectively shape the oxidative proteome. The potential of ROS/RNS scavenging enzymes to shape the oxidative proteome is clearly illustrated by the GSNO scavenger GSNOR1. In the absence of functional GSNOR1, cellular levels of GSNO and consequently, protein S-nitrosylation markedly increase, especially upon pathogen infection (Feechan et al., 2005; Yun et al., 2011).

While these scavenging enzymes are important in directly regulating ROS/RNS and oxidative stress, particularly during pathogen infection, there is another group of enzymes, known as oxidoreductases or redoxins, that are responsible for direct reversal of ROS/RNS-induced oxPTMs. These enzymes belong to the superfamily of thioredoxins that are emerging as central players in selective redox signaling.

**Thioredoxin-mediated immune responses**
Thioredoxins (TRXs) are a superfamily of oxidoreductase enzymes. They are made up of conventional TRXs, glutaredoxins (GRXs), nucleoredoxins (NRXs), and protein disulphide isomerases (PDIs) (Marchal et al., 2014; Meyer et al., 2008). Conventional TRXs have a conserved active site sequence WC(G/P)PC (Meyer et al., 2008). One of the key functions of conventional TRX enzymes is to reduce disulfide bonds in target proteins. Disulfide bridges are reduced by a dithiol mechanism; the first active-site Cys covalently binds to the Cys of the target protein to form a mixed disulfide, before the second active-site Cys resolves the mixed disulfide, thereby releasing the reduced target protein while rendering the TRX active-site Cys residues oxidised (i.e. disulfide bridge). Over the last several years it has become clear that TRXs not only reduce disulfides but also other oxidised Cys forms, including S-nitrosothiols and sulfenic acids, via either heterolytic or homolytic cleavage reactions (Benhar et al., 2008; Kneeshaw et al., 2014; Tarrago et al., 2010). TRX activity is recycled by NADPH-dependent thioredoxin reductases (NTR) or ferredoxin-dependent thioredoxin reductases (FTR) that reduce oxidised TRXs by donating electrons to NAD(P)H (Figure 1).

The TRX family has been shown to play diverse mechanistic roles in plant immune responses. Their mechanisms of action range from exhibiting direct anti-microbial activity, to reversing oxPTMs to either enable signaling or to protect critical proteins from the damaging effects of oxidation. With regard to the former, OsTRXm and the TRX-like protein OsTDX from Oryza sativa were found to display anti-microbial activity (Park et al., 2019a, 2019b). OsTRXm was identified as a novel antifungal protein, inhibiting the growth of several fungi, including the maize pathogen Fusarium moniliforme (Park et al., 2019b). Although TRXh5 is not secreted and thus not considered to be a natural antifungal protein, recombinant TRXh5 from Arabidopsis was found to display antifungal properties. Interestingly, when the yeast Candida albicans was treated with AtTRXh5, it exhibited an increase in ROS generation, suggesting that TRXh5 inhibited fungal growth by eliciting ROS production (Park et al., 2017). The identification of antifungal properties associated with TRXh5 suggests that there is scope for using its redox properties as a biotechnological crop improvement strategy.
TRXh5 and closely related TRXh3 have also emerged as major regulators of plant immune signaling (Kneeshaw et al., 2014; Laloi et al., 2004; Tada et al., 2008). Specifically, these TRX regulate the conformational state and thus activity of the NPR1 immune transcriptional activator. As described above, in resting cells NPR1 exists in an oligomeric form in the cytoplasm bound together by disulfide bridges. Upon pathogen-induced SA accumulation, TRXh3/h5 facilitate NPR1 disulfide reduction and associated monomerization. Moreover, TRXh5 directly denitrosylates NPR1, which prevents the formation of further disulfide bridges (Kneeshaw et al., 2014; Tada et al., 2008). Consequently, TRXh5 plays a critical role in NPR1-dependent transcriptional reprogramming.

In addition to regulating protein signaling, TRXs have been shown to exhibit protective roles in immunity. This was shown recently for the immune inducible TRX family member Nucleoredoxin 1 (NRX1) that can be found in both the cytoplasm and nucleus (Marchal et al., 2014). The nrx1 knock-out mutant displays autoimmune traits and has increased resistance to P. syringae compared to wild-type Arabidopsis (Kneeshaw et al., 2017). Using a substrate-trapping approach, NRX1 was found to target H$_2$O$_2$ scavenging enzymes, including all three Arabidopsis catalases and APX1, all of which play roles in the immune response (Kneeshaw et al., 2017). The authors showed that CAT2 oxidation in response to bacterial infection was enhanced in the nrx1-1 knockout mutant, which correlated with a decrease in catalase activity. Moreover, recombinant NRX1 could rescue catalase activity of nrx1-1 cell extracts. These findings demonstrate that NRX1 prevents inhibitory oxidation of catalases, thereby guarding them from the ROS-rich environments they function in. Taken together with the fact that TRX family members play essential roles in recycling the activity of peroxiredoxins (PRX) that also scavenge H$_2$O$_2$, it appears justified to conclude that protection of ROS scavengers and probably other types of proteins is a general function of TRX family members.

So how are the activities of TRX enzymes regulated? Little remains known about the regulation of TRX. In addition to regulation of TRX gene expression, TRX enzymes may also be redox regulated. Plant and human TRXf and TRX-1, respectively, are regulated by
glutathionylation. Glutathionylation decreases the ability of plant TRXf to be reduced by ferredoxin-thioredoxin reductase, while human TRX-1 was inactivated. These findings suggest that cellular redox status can control the activity of some TRX enzymes, but this may not be a widespread mechanisms utilised by all TRX enzymes (Casagrande et al., 2002; Michelet et al., 2005).

TRX substrate specificity in the immune response

In contrast to other organisms, plant genomes encode numerous TRXs. The high number of TRXs in plants and the range of locations in the cell suggest that they have specific cellular functions and substrates (Fernandes and Holmgren, 2004; Geigenberger et al., 2017). TRXs are characterised by their highly conserved active site sequence and relatively large groups of members residing in the same subcellular location. So do TRX act selectively and if so, what determines their substrate specificity?

As there is redundancy between TRXs as well as between the GRX and TRX systems (Reichheld et al., 2009), knockout mutants often do not show the full extent of TRX function, thereby preventing identification of specific substrate repertoires. One method of studying TRX substrate selectivity is by overexpressing them in redox-perturbed mutants. The effectiveness of this approach was demonstrated by overexpression of immune-induced TRXh5 in two different protein-SNO accumulating backgrounds: gsnor1 and nox1 mutants that respectively overaccumulate GSNO and free NO (Kneeshaw et al., 2014). In response to P. syringae infection, TRXh5 expression selectively rescued immune deficiencies in nox1 but not gsnor1. This was due to selective denitrosylation of protein-SNO, as TRXh5 localised to similar subcellular locations but decreased protein-SNO concentrations only in nox1 mutants. These findings indicate that TRXh5 can distinguish between protein-SNO derived from free NO as opposed to GSNO.

How exactly such substrate specificity is established remains poorly understood, but several recent studies on molecular characteristics of both TRXs and their substrates are now beginning to shed light on this. It has been shown that stereochemistry and structure of
NO donors is a major determinant in selective S-nitrosylation, due to Cys accessibility in the 3D structure of target proteins (Foster et al., 2009). It is therefore reasonable to assume that the structural conformation of substrates will play an important role in their selection by specific TRXs. In accordance, domain swapping between TRXs enhanced their antifungal activity, showing that structural differences between TRXs can lead to functional changes (Kim et al., 2019). Moreover, it was shown that due to conformational restrictions imposed by disulfides on the substrate, TRXs recognise oxidised Cys with greater efficiency than its reduced counterpart (Palde and Carroll, 2015). If this is also true for oxidation states other than disulfide bonds remains to be explored. Another possibility is that specificity is determined through electrostatic complementarity between TRX and its substrate. Although the TRX active site is evolutionarily highly conserved, the electrostatic potential of the surrounding solution-exposed surfaces shows variation. Gellert et al. (2019) assessed the primary and tertiary structure of human TRXs and GRXs, and found that primary and tertiary structure did not contribute to substrate specificity. Instead, they show that TRX/GRX could be grouped based on the positive or negative electrostatic potentials of their water-accessible surfaces, suggesting this may determine substrate specificity. Indeed, the *Chlamydomonas reinhardtii* TRX CrTRXf1 was shown to have an electrostatic positive crown that corresponds to the electronegative surfaces surrounding the cysteines of its substrates FBPase and SBPase (Lemaire et al., 2018), adding weight to this hypothesis. Hence, a combination of localisation, structural accessibility or flexibility, and electrostatic complementarity will likely determine specific TRX substrate repertoires (Figure 2).

**PATHOGENS MANIPULATE AND HIJACK REDOX-DEPENDENT IMMUNE RESPONSES**

Redox-mediated immune responses to pathogen infection effectively prevent pathogen spread. However, the arms race between pathogen and host can lead to pathogens overcoming host defence responses. Recent evidence indicates that pathogens not only utilise their own redox systems to cope with host immune responses (Box 2) (Dubreuil et al.,
but they also manipulate and exploit cellular redox responses of the host.

The production of ROS and RNS are important weapons of eukaryotic immune systems, either directly killing pathogens by causing oxidative stress or by activating host immune signaling. Consequently, many pathogens have evolved effector proteins that suppress the immune-induced oxidative burst. For example, the *P. syringae* effector HopM1, which targets vesicle trafficking, was shown to also inhibit the immune-induced ROS burst via a proteasome-dependent pathway (Lozano-Durán et al., 2014). Indeed, HopM1 interacts with proteasomes and inhibits their proteolytic activity (Üstün et al., 2016). Moreover, several *P. syringae* effectors suppress receptor-like kinases that activate NADPH oxidases and thus circumvent not only pathogen perception, but also the damaging effects of the ROS burst (Xin et al., 2018). Some pathogen effectors directly alter the activity of plant redox enzymes. For example, Pep1 is a conserved fungal effector of smut-causing fungi on cereals and was found to directly inhibit the activity of apoplastic plant peroxidases, thereby boosting pathogen virulence by suppressing the apoplastic ROS burst (Hemetsberger et al., 2015).

In addition, ROS scavenging enzymes, including catalases and glutathione S-transferases, have been identified during infection as pathogen- and parasite-secreted proteins (Blackman and Hardham, 2008; Dubreuil et al., 2007; Guo et al., 2012; Tanabe et al., 2010; Zhang et al., 2004). These enzymes may function as effectors that enable pathogen survival in hostile, oxidative host environments. Non-enzymatic antioxidants, such as the carbohydrate mannitol, are also secreted by some pathogens and may also combat the antimicrobial effects caused by high levels of ROS/RNS in host cells (Jennings et al., 2002; Voegele et al., 2005; Williamson et al., 2013). Thus, pathogen manipulation of host redox responses appears to be a widespread mechanism for promoting pathogen virulence.

Recent studies have shown that pathogen effectors also suppress ROS production by targeting the chloroplast, leading to associated reductions in programmed cell death, photosynthesis, electron transport, and PSII activity (de Torres Zabala et al., 2015;
Rodríguez-Herva et al., 2012; Xu et al., 2019). This was further demonstrated in case of the *Phytophthora infestans* effector AVRvnt1 and its NLR immune receptor Rpi-vnt1.1, which activates immunity in a light-dependent manner (Gao et al., 2020). The authors reported that in Solanaceous plants, the AVRvnt1 effector interacted with the nuclear-encoded chloroplast protein Glycerate Kinase (GLYK), which was required for Rpi-vnt1.1-mediated immunity. GLYK was found to be a positive regulator of plant immunity, but exposure to light was required to produce full-length GLYK, including its chloroplast transit peptide. AVRvnt1 prevented the accumulation of GLYK and may intercept GLYK trafficking to the chloroplast. As GLYK is involved in energy production and photorespiration, the perturbation of canonical GLYK activity by AVRvnt1 likely alters redox-mediated immune responses in the chloroplast by interfering with energy production.

Pathogens have also evolved ways to hijack redox-mediated immune responses through manipulation of host TRX systems. The RipAY effector from the plant pathogen *Ralstonia solanacearum* functions as a γ-glutamyl cyclotransferase (GGCT), responsible for degradation of the cellular antioxidant glutathione that is required for immunity (Dubreuil-Maurizi et al., 2011). Interestingly, RipAY was found to interact with host TRXh3 and TRXh5, which were required for its activation and for the resulting degradation of glutathione and inhibition of immune responses (Fujiwara et al., 2016; Mukaihara et al., 2016; Sang et al., 2018). Both active site Cys residues of TRXh5 were required for interaction with RipAY and for its activation, indicating that *R. solanacearum* exploits the redox-sensing or oxidoreductase activity of host TRXs (Fujiwara et al., 2020, 2016).

Nematode effectors also target ROS-scavenging TRX systems of their hosts. The effector MjTTL5 secreted by the nematode *Meloidogyne javanica* was shown to interact with the Arabidopsis ferredoxin-thioredoxin reductase catalytic subunit (AtFTRc). Mutational analyses showed that MjTTL5 and host AtFTRc both enhanced nematode susceptibility (Lin et al., 2016). Moreover, MjTTL5 suppressed the immune-induced ROS burst, suggesting that it exploits host AtFTRc to promote ROS scavenging and decrease oxidative stress. Similarly, the root-knot nematode *Meloidogyne incognita* was reported to overcome
resistance by potentially exploiting peroxidases in tomato plants. Whereas resistant tomato plants carry the Mi-1 resistance gene, susceptible varieties of tomato show higher expression of genes involved in ROS scavenging, including glutathione S-transferase (SIGST) and peroxidase (SIPOD). Silencing of SIPOD in Mi-1 carrying resistant varieties, resulted in an enhanced ROS burst upon infection in conjunction with a decrease in female nematode formation and egg mass, suggesting that M. incognita and probably other root-knot nematodes may confer susceptibility by exploiting ROS scavenging activities of host peroxidases (Guan et al., 2017).

As an alternative to suppressing ROS accumulation, it has been shown that effectors of necrotrophic pathogens specifically target the plant TRX system to induce cell death responses. Victorin, a fungal effector of Cochliobolus victoriae, the pathogen responsible for Victoria blight in oat, specifically targets Arabidopsis TRXh5. Victorin binds to TRXh5 via the first Cys of its active site (Cys39), resulting in inhibition of TRXh5 activity (Sweat and Wolpert, 2007). This is recognised by the NB-LRR, LOV1 (Locus Orchestrating Victorin effects 1), which guards TRXh5, and in turn activates programmed cell death (Lorang et al., 2012, 2007; Sweat and Wolpert, 2007). As necrotrophs kill host cells before feeding, TRXh5-victorin induced cell death promotes disease susceptibility to C. victoriae. Consequently, victorin inhibits TRXh5 activity and can cause susceptibility to biotrophic pathogens, providing a clue as to why LOV1 guards TRXh5 and demonstrating that C. victoriae hijacks a redox-dependent immune response to biotrophs to promote its own virulence. Moreover, these findings suggest that TRX enzymes may be more widely targeted by pathogen effectors.

Conclusions
Redox-based signaling is a vital part of plant immune responses and new redox mechanisms are continuously being discovered. Recent studies have provided new insights and hypotheses of how ‘redox sensors’ may be regulated during the plant immune response by the type of ROS/RNS they are exposed to, and by specific ROS/RNS scavenging
enzymes and TRXs. However, how these vast networks are controlled and enable selective signaling remains largely unknown (see Outstanding Questions). Through understanding the specificities and redundancies of redox signaling within the immune response in conjunction with other environmental stresses, it will be possible to uncover how responses to pathogen infection may be affected by a changing environment and how pathogens may take advantage of this. The development of new proteomic techniques has started to reveal a vast array of redox-sensitive proteins that hopefully will lead to new discoveries of how selective redox signaling networks orchestrate the plant immune response.

ACKNOWLEDGEMENTS

J.R.B. was supported by an EASTBIO Doctoral Training partnership (BB/M010996/1) from the Biological and Biotechnology Research Council (BBSRC) and S.H.S by a grant from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement No 678511).
Box 1: Cross-regulation of ROS/NO signaling

Increasing evidence has shown there is cross-talk between ROS and NO to tightly control redox signaling responses, including programmed cell death (Astier et al., 2018). Following infection with an avirulent strain of *P. syringae*, treatment with the NO donors GSNO or CysNO substantial decreased NADPH oxidase activity, indicating that that NO negatively regulates NADPH-mediated ROS production upon pathogen infection (Yun et al., 2011). Further analysis showed that RBOHD is S-nitrosylated at Cys890 and its mutation enhanced RBOHD activity in response to pathogen infection, further demonstrating that ROS/NO signaling is interlinked.

Additionally, early oxPTMs that function upstream of RBOHD-mediated ROS production may control downstream redox signaling mechanisms. Receptor-like kinases (RLKs) regulate RBOHD-mediated ROS production (Kimura et al., 2020, 2017); however it has also been suggested that RLKs themselves may be redox regulated. The cysteine-rich receptor kinase (CRK) subfamily of RLKs contain a high number of conserved Cys residues, suggesting that CRKs may be targets of redox regulation. In accordance, Lee et al. (2017) showed that overexpression of CRK36 enhanced the cell death response and increased stomatal immunity and resistance to hemibiotrophic as well as necrotrophic pathogens, but overexpression of a Cys mutant abolished responses. Furthermore, the authors showed that CRK36 interacted with the receptor-like cytoplasmic kinase BIK1, which is responsible for activating RBOHD upon PAMP-perception, suggesting that early redox modifications of CRKs could control downstream ROS production.

H₂O₂ and NO have also been detected in distal tissues following infection, and mutants compromised in ROS or NO biosynthesis were found to be compromised in systemic acquired resistance (SAR), indicating ROS/NO signaling is also involved in long-distance
immune signaling (Wang et al., 2014). Interestingly, NO levels in the ROS biosynthesis mutant *rbohF* were undetectable after pathogen infection, likewise the NO biosynthesis mutant *noa1 nia2* displayed reduced levels of ROS after pathogen infection, suggesting that ROS/NO-mediated SAR is interdependent and may be regulated by a ROS/NO feedback loop (Wang et al., 2014).

**Box 2: Pathogen TRX systems aid virulence**

Emerging evidence shows pathogens utilise TRX systems of their own, which can enhance their ability to infect host plants. Both the nematode *Meloidogyne incognita* and the bacterium *Candidatus Liberibacter asiaticus* utilise TRX-dependent PRXs to enable infection (Dubreuil et al., 2011; Jain et al., 2018). Additionally, putative protein disulphide isomerases have also been identified in plant parasitic nematodes (PPNs), including *Heterodera schachtii* and *Globodera pallida* (Gross et al., 2020; Habash et al., 2017). Recently the *G. pallida* effector GpPDI1 was characterised as a functional thioredoxin. When transiently expressed in *Nicotiana benthamiana* and tomato it was found to induce cell death, however it was also found that its enzymatic activity was not required for the host elicitation of cell death, which suggests its TRX-like activity may not be required for host recognition (Gross et al., 2020).

Although necrotrophic pathogens can benefit from ROS/RNS induced cell death in the host, they still need to find a way to function in highly oxidative environments, suggesting they may require their own TRX systems. This has been demonstrated in the necrotrophic pathogen *Scelortinia sclerotiorum*, which required the TRX reductase SsTrr1 for increased oxidative stress tolerance and virulence (Zhang et al., 2019). Exogenous H$_2$O$_2$ treatment of SsTrr1-silenced strains resulted in inhibition of hyphal growth and decreased virulence in Arabidopsis and *N. benthamiana*, suggesting that it is crucial for surviving the ROS burst upon infection (Zhang et al., 2019). Similar results were obtained for *Botrytis cinerea* in that knockout of *BcTRX1* and *BcTRX2* weakened virulence, while increasing sensitivity to
oxidative stress. Together these findings indicate that pathogen TRX systems are highly important for aiding pathogen virulence (Viefhues et al., 2014).
FIGURE LEGENDS

Figure 1. Localisation and mechanisms of ROS/RNS production (signified by stars) and examples of known antioxidants and TRXs. ROS/RNS are produced in different subcellular locations, as are the antioxidant enzymes and oxidoreductases responsible for maintaining cellular redox homeostasis and reversal of oxidative protein modifications. Different cellular localisation is indicative of selectivity and specificity in redox signaling.

AO, Ascorbate Oxidase; APX, Ascorbate Peroxidase, thylakoid (tAPX) and cytosolic (cAPX); Asc, Ascorbate; CAT, Catalase; GPX, Glutathione Peroxidase; GR, Glutathione Reductase; GRX, Glutaredoxin; MDHA, Monodehydroascorbate; NTR, NADPH-dependent TRX Reductase; PRX, Peroxidase; RBOH, Respiratory Burst Oxidative Homologs; SOD, Superoxide Dismutase; TRX, Thioredoxin. Figure 2. Selective redox signaling in the immune response. Upon pathogen perception, different forms of ROS/RNS are generated, resulting in oxidative modifications of the reactive free thiols of ‘redox sensitive’ proteins. Modified proteins may be involved in specific ROS/RNS-mediated signaling pathways, or overlap with different pathways. These modifications can be reversed by specific TRXs, adding an additional layer of selective regulation to ROS/RNS-mediated signaling. TRXs may also display selective tendencies for targets involved in specific pathways or display more general reductive activities. Created with BioRender.com

Chloroplast-generated reactive oxygen species play a major role in localized cell death during the non-host interaction between tobacco and Xanthomonas campestris pv. vesicatoria. The Plant Journal 60, 962–973. https://doi.org/10.1111/j.1365-313X.2009.04010.x
Recent evidence highlights the importance of chloroplast-generated ROS production in response to pathogen infection.

TRXs may confer selective redox signaling through chemical features and electrostatic complementarity.

New proteomic tools are beginning to uncover selective ROS/RNS signaling dynamics and the plant immune ‘redoxome’.

Recent studies are advancing our understanding of how pathogens manipulate host redox systems.
OUTSTANDING QUESTIONS

- How are redox signaling pathways rendered specific and reversible?
- Can newly emerging proteomic tools uncover the full extent of TRX redundancy and specificity in the plant immune response?
- To what extent do pathogens manipulate plant TRX systems?
- How do additional environmental stresses affect redox signaling networks of the plant immune response?
BOX 1. Cross-regulation of ROS/NO signaling

Increasing evidence has shown there is cross-talk between ROS and NO to tightly control redox signaling responses, including programmed cell death (Astier et al., 2018). Following infection with an avirulent strain of P. syringae, treatment with the NO donors GSNO or CysNO substantially decreased NADPH oxidase activity, indicating that NO negatively regulates NADPH-mediated ROS production upon pathogen infection (Yun et al., 2011). Further analysis showed that RBOHD is S-nitrosylated at Cys890 and its mutation enhanced RBOHD activity in response to pathogen infection, further demonstrating that ROS/NO signaling is interlinked.

Additionally, early oxPTMs that function upstream of RBOHD-mediated ROS production may control downstream redox signaling mechanisms. Receptor-like kinases (RLKs) regulate RBOHD-mediated ROS production (Kimura et al., 2020, 2017); however it has also been suggested that RLKs themselves may be redox regulated. The cysteine-rich receptor kinase (CRK) subfamily of RLKs contain a high number of conserved Cys residues, suggesting that CRKs may be targets of redox regulation. In accordance, Lee et al. (2017) showed that overexpression of CRK36 enhanced the cell death response and increased stomatal immunity and resistance to hemibiotrophic as well as necrotrophic pathogens, but overexpression of a Cys mutant abolished responses. Furthermore, the authors showed that CRK36 interacted with the receptor-like cytoplasmic kinase BIK1, which is responsible for activating RBOHD upon PAMP-perception, suggesting that early redox modifications of CRKs could control downstream ROS production.

H₂O₂ and NO have also been detected in distal tissues following infection, and mutants compromised in ROS or NO biosynthesis were found to be compromised in systemic acquired resistance (SAR), indicating ROS/NO signaling is also involved in long-distance immune signaling (Wang et al., 2014). Interestingly, NO levels in the ROS biosynthesis mutant rbohF were undetectable after pathogen infection, likewise the NO biosynthesis mutant noa1 nia2 displayed reduced levels of ROS after pathogen infection, suggesting that ROS/NO-mediated SAR is interdependent and may be regulated by a ROS/NO feedback loop (Wang et al., 2014).
Emerging evidence shows pathogens utilise TRX systems of their own, which can enhance their ability to infect host plants. Both the nematode *Meloidogyne incognita* and the bacterium *Candidatus Liberibacter asiaticus* utilise TRX-dependent PRXs to enable infection (Dubreuil et al., 2011; Jain et al., 2018). Additionally, putative protein disulphide isomerases have also been identified in plant parasitic nematodes (PPNs), including *Heterodera schachtii* and *Globodera pallida* (Gross et al., 2020; Habash et al., 2017). Recently the *G. pallida* effector GpPDI1 was characterised as a functional thioredoxin. When transiently expressed in *Nicotiana benthamiana* and tomato it was found to induce cell death, however it was also found that its enzymatic activity was not required for the host elicitation of cell death, which suggests its TRX-like activity may not be required for host recognition (Gross et al., 2020).

Although necrotrophic pathogens can benefit from ROS/RNS induced cell death in the host, they still need to find a way to function in highly oxidative environments, suggesting they may require their own TRX systems. This has been demonstrated in the necrotrophic pathogen *Scelortinia sclerotiorum*, which required the TRX reductase SsTr1 for increased oxidative stress tolerance and virulence (Zhang et al., 2019). Exogenous \( \text{H}_2\text{O}_2 \) treatment of SsTr1-silenced strains resulted in inhibition of hyphal growth and decreased virulence in Arabidopsis and *N. benthamiana*, suggesting that it is crucial for surviving the ROS burst upon infection (Zhang et al., 2019). Similar results were obtained for *Botrytis cinerea* in that knockout of *BcTRX1* and *BcTRX2* weakened virulence, while increasing sensitivity to oxidative stress. Together these findings indicate that pathogen TRX systems are highly important for aiding pathogen virulence (Viefhues et al., 2014).
