ABSTRACT

We report the transition towards a type 1 Seyfert experienced by the classical type 2 Seyfert nucleus in NGC 7582. The transition, found at most 20 days from its maximum peak, presents a unique opportunity to study these rare events in detail. At maximum the Hα line width is of about 12000 km s\(^{-1}\). We examine three scenarios that could potentially explain the transition: capture of a star by a supermassive black hole, a reddening change in the surrounding torus, and the radiative onset of a type IIn supernova exploding in a compact nuclear/circumnuclear starburst.

Subject headings: galaxies: active - galaxies: individual: NGC 7582 - galaxies: Seyfert - galaxies: starburst - supernova remnants
1. Introduction

The last decade has seen a significant advance in our way of understanding the phenomenology of various classes of Active Galactic Nuclei (AGN) under the concept of orientation (see Antonucci 1993 for a review). Unified schemes postulate the existence of a dusty obscuring torus that hides both the Broad Line Region (BLR) and the continuum emitting zone when seeing the nuclear region of an AGN edge-on. Seyfert 2 and 1 nuclei would then be exactly the same kinds of objects but viewed from different angles, such that the line of sight crosses or not the dusty torus. This configuration can explain several observables of Seyfert 2 nuclei, like the detection of broad lines in polarized light at optical wavelengths (Antonucci & Miller 1985, Miller & Goodrich 1990), which are directly detected in near-IR light (Goodrich, Veilleux & Hill 1994), the presence of kpc scale ionizing cones (Pogge 1988, 1989, Tadhunter & Tsvetanov 1989), and the steepening and excesses of far-IR colours (Maiolino et al. 1995, Spinoglio et al. 1995, Pérez García, Rodríguez-Espinosa & Santolaya Rey 1998).

A problem still arises when analyzing in detail where the blue continuum observed in Seyfert 2 nuclei comes from. Classically, this was regarded to be light scattered by dust or hot electrons in the ionized region illuminated by the nucleus. However, the different polarization levels of broad lines and continuum (e.g. Miller & Goodrich 1990, Tran, Miller & Kay 1992) and the absence of residual broad lines in directly received optical light argue in favour of the existence of a second continuum source, most probably a region of star formation that surrounds the dusty torus (Goodrich 1989a, Cid Fernandes & Terlevich 1995; Heckman et al. 1995). Starbursts in the nuclei of Seyfert 2 galaxies have indeed been detected through near-IR photospheric absorption features characteristic of red supergiant stars (Terlevich, Díaz & Terlevich 1990; Oliva et al. 1995). Some of these dominate the observed continuum from the near-UV to the near-IR, and have resolved sizes of a few
hundreds of pc (Heckman et al. 1997; Colina et al. 1997; González Delgado et al. 1998).

NGC 7582 is a classical Seyfert 2 nucleus, as indicated by the relatively high excitation measured from the $[\text{O II}]\lambda3727\,\text{Å}/[\text{OIII}]\lambda5007\,\text{Å}$ ratio plus the simultaneous presence of strong $[\text{Ne V}]\lambda3425\,\text{Å}$, $\text{He II}\lambda4686\,\text{Å}$, $[\text{O I}]\lambda6300\,\text{Å}$ and $[\text{N II}]\lambda\lambda6548/6584\,\text{Å}$ lines. Many of the nuclear properties in NGC 7582 also support a unified scheme. A sharp-edged $[\text{O III}]$ outflow in the form of a cone is observed (Morris et al. 1985, Storchi-Bergmann & Bonatto 1991). Optical spectropolarimetry does not reveal any hidden BLR, but since the far-IR colours $60\,\mu\text{m} - 25\,\mu\text{m}$ are very red, the absence has been taken as support for an edge-on thick torus able to block even the light scattered towards the observer (Heisler, Lumsden & Bailey 1997). Indeed a large column density of neutral H also blocks the hard X-rays, implying a large obscuration (Warwick et al. 1993).

The presence of stars in the nucleus is now firmly established. Morris et al. (1985) found a steep gradient of Ha perpendicular to the $[\text{O III}]$ cone, which they interpret as a 1 kpc disk of H II regions oriented at $60^\circ$ from the plane of the galaxy (see their Figure 10). The CO absorption lines and large near-IR light-to-mass ratio are similar to those of H II galaxies and a factor of 5 larger than those of normal galaxies, indicating that red supergiants dominate the light of the inner 200 pc at those wavelengths (Oliva et al. 1995).

This letter analyzes new spectroscopic and surface photometry data that show that NGC 7582 has experienced a transition to a Seyfert 1 stage. This transition is a challenge to reconcile with unification schemes since the IR to X-ray data indicate that we are viewing the nucleus through a large column of obscuring material.
2. Data acquisition and analysis

Three spectra of NGC 7582 were obtained at ESO-La Silla with the Danish 1.54m and ESO 3.6m telescopes from 1998 July 11th to October 21st. The journal of observations in Table 1 contains the relevant information regarding set-ups and exposure times. The slit was always centered on the nucleus of the galaxy and oriented at 24° PA. The total integration time per night was split in two or three integrations in order to be able to remove the effect of cosmic rays in the co-added final spectrum. Standard stars were observed all nights, except on October 6th. The frames have a scale of 0.39 arcsec/pixel with the 1.54m telescope and 0.15 arcsec/pixel with the 3.6m.

The data were reduced using the IRAF software package in a standard way. The CCD frames were first bias subtracted and then flat-field corrected. Wavelength calibration with He+Ar lamps and flux calibration with the corresponding stars was then performed, and the sky was subtracted using the outermost parts of the slit.

The spectra were internally flux-calibrated to the same relative scale using [N II]\(\lambda 6583\) Å and, independently, also [O III]\(\lambda 5007\) Å, under the standard assumption that the flux of the narrow forbidden lines of AGN does not vary on such short time-scales (e.g. Korista et al. 1995).

Two \(R\)-band images of 30 and 90 s were also obtained on July 11th and October 21st with the same telescope configuration. The reduction involved bias subtraction and flat-fielding. Calibration with a photometric standard star was obtained relative to the field stars of the frames.

Figure 1 displays spectra that we extracted binning pixels along the spatial direction over 2 arcsec, which corresponds to 150 pc at the recession velocity of the galaxy \(v_r = 1575\) km s\(^{-1}\) (de Vaucouleurs et al. 1991) for \(H_0 = 50\) km s\(^{-1}\) Mpc\(^{-1}\). The top
panel shows a spectrum of NGC 7582 taken well before the transition (Cid Fernandes, Storchi-Bergmann & Schmitt 1998). This remained unchanged as a Seyfert 2 spectrum until at least 1998 June 20th (Halpern, Kay & Leight 1998). Note that the spectrum of October 6th is not flux-calibrated.

The spectrum of July 11th clearly shows broad Hα, Hβ, Na I and Fe II emission, absent in the previous record. The broad component of the Balmer emission lines is well represented by a single gaussian of FWHM=12400 km s$^{-1}$ blue-shifted by 1980 km s$^{-1}$ with respect to the narrow FWHM=260 km s$^{-1}$ lines. By October 6th, the broad Hβ has disappeared, but broad Fe II, Na I and a prominent Hα of FWHM=7870 km s$^{-1}$ is still present, redshifted by 1570 km s$^{-1}$ with respect to the narrow lines. The October 21st spectrum shows a further decline of the broad Hα line to FWHM=6660 km s$^{-1}$. It should be noted that although the broad Hβ line is not apparent in the spectra after October 6th, when the bulge population is subtracted, a very weak broad line is indeed present.

The continuum flux of the nucleus at $\lambda$6260 Å decreases by a 50% between July 11th and October 6th, and increases by a 30% between October 6th and 21st.

In order to check if the transition is really nuclear we have calculated the astrometry of the nucleus relative to field stars in our $R$-band images obtained after the transition, and in an archival image taken on 1995 June 16th (before the transition) with the Wide Field Planetary Camera 2 (WFPC2) of the Hubble Space Telescope (HST). We find that the centroid of the nucleus is at the same position, inside an error box of 0.16 arcsec, i.e. 12 pc.

3. Discussion

Figure 1 shows that shortly before July 11th the nucleus of NGC 7582 developed broad permitted lines characteristic of a Seyfert 1 nucleus (Joguet, Kunth & Terlevich 1998).
While variability is a common characteristic of Seyfert 1 nuclei and QSOs, which are known to undergo prominent variations (e.g. Peterson 1993) that lead even to the temporal disappearance of broad lines (e.g. Antonucci & Cohen 1983, Penston & Pérez 1984, Alloin et al. 1986), it is actually a rarity among Seyfert 2 and LINERS. Apart from the transition experienced by NGC 7582, reported here, three other classical Seyfert 2 nuclei and one LINER developed broad lines in the past: Mrk 6 (Khachikian & Weedman 1971), Mrk 993 (Tran, Osterbrick & Marel 1992), Mrk 1018 (Cohen et al. 1986) and NGC 1097 (Storchi-Bergmann, Baldwin & Wilson 1993). The nucleus of NGC 7582 is however the only one caught in fraganti at such an early stage in the transition.

In some cases the sudden development of broad lines has been interpreted in the literature as transients associated with the disruption and capture of stars by a supermassive black hole. The frequency of such events in a normal spiral galaxy is predicted to be $10^{-4}$ yr$^{-1}$ (Rees 1988). The number of narrow-lined AGN registered in the Véron-Cetty & Véron catalogue (1998) is 701, including those with reported obscured or scattered broad-lines. The probability of five of them undergoing a capture phenomenon in the last 30 years is 4%, assuming a Poissonian temporal distribution of the captures and a continuous monitoring or long-lasting events. In the case of NGC 7582 this could be possible if the idea of the dusty torus around the nucleus is dropped. A torus would otherwise block all the optical light coming from the surroundings of the black hole.

As a matter of fact two of the transition cases mentioned above (Mrk 993 and Mrk 1018) have been proposed to be explained in the framework of unification by patchy dusty tori that suddenly let the nuclei be directly seen through regions with small covering factors or light obscuration. Goodrich (1989b, 1995) finds evidence for a very weak, previously unnoticed, broad Hα line before the transitions to Seyfert 1 stages in these two nuclei and argues that the flux changes derived from continuum bands and broad lines at
different wavelengths are consistent with the simple hypothesis of a change in reddening. In the case of NGC 7582 the BLR reddening before and after the transition cannot be checked since we find no evidence of a weak broad line before the transition. The continuum change measured at \( \lambda 5026 \) Å and \( \lambda 6260 \) Å is however inconsistent with a reddening change given by a local reddening law: the fluxes at \( \lambda 5026 \) Å of the 1994 January 6th and 1998 July 11th spectra, after bulge subtraction, imply \( \Delta E_{B-V} \approx 0.3 \) mag, and at \( \lambda 6260 \) Å \( \Delta E_{B-V} \approx 1.3 \) mag. Some residual stellar light must still be present here since young stellar populations are located near the nucleus. Schmitt, Storchi-Bergmann & Cid Fernandes (1998) account these to be at least a 6% of the total nuclear light. If we assume a continuum shape typical of starbursts, \( f_{\nu} \propto \nu^{\beta} \) with \( \beta \approx 0 - 1 \) at an age \( \lesssim 10^7 \) yr (e.g. Leitherer et al. 1999), we still have reddening changes ranging \( \Delta E_{B-V} \approx 1.1 \) to 2.3 mag at \( \lambda 5026 \) Å and \( \Delta E_{B-V} \approx 3.3 \) to 3.5 mag at \( \lambda 6260 \) Å, inconsistent with one another. Furthermore, it would be difficult to understand how the BLR light has managed to traverse a torus with about 200 mag of extinction (\( A_V \)), as derived from X-rays absorptions. However, the column density of absorbing material has been reported to change even a factor of 3 in the last 13 years (Warwick et al. 1993, Xue et al. 1999). X-ray data will shed new light into the possibility of a reddening change in the torus. Possible caveats of the optical estimations are, one one hand, that these are based on the local reddening law and, on the other, that the contamination of the young nuclear/circumnuclear stellar component has been removed through modeling in the absence of high spatial resolution and/or a wider spectral coverage.

A more fundamental concern in this analysis is whether the BLR and the continuum light will actually be crossing the same obscuring regions of the torus. In principle, a model could be built in which the BLR light might pass through clearance zones not reached by the continuum light. This, however, seems rather ad hoc.

An alternative possibility to explain the transition can be found resourcing to
phenomena that might occur around the torus, and which are not necessarily related to the central engine of the AGN. The nuclear/circumnuclear starburst, detected at a radius $r < 100$ pc (Oliva et al. 1995), is a possible source since it must produce supernova (SN) explosions.

From an age $10 \to 60$ Myr, a starburst sustains a SN rate directly proportional to the blue light emitted by the stars in the cluster (Aretxaga & Terlevich 1994). The luminosity of the inner 3 arcsec of NGC 7582 before the transition is $V = 15$ mag (Kotilainen, Ward & Williger 1993). The luminosity profile at this stage is not very peaked, as shown in HST images (Malkan, Gorjian & Tam 1998), where the luminosity of the nucleus changes by 3 mag when using apertures ranging from 0.5 to 0.1 arcsec. The stellar populations of the nucleus at optical wavelengths are best represented by old ages ($t > 100$ Myr) with a 6 to 12% contamination by a reddened $E_B - V \approx 0.6$ mag starburst + featureless continuum (Schmitt et al. 1998). Therefore, the intrinsic luminosity of the starburst nucleus is about $M_B \approx -17$ mag and the SN rate would then be $\nu \approx 0.02$ yr$^{-1}$. If all the SN explosions generate broad lines, there is a 33% probability of having detected a transition to a Seyfert 1 stage in the last 30 yr.

A typical SN can increase the luminosity of the host cluster by about 2 mag. Classical type II SN, however, show spectral features, like P-Cygni profiles, which do not compare with the observed gaussian profiles of the Balmer lines in NGC 7582. The only possible exception could be SN 1983K, which showed prominent broad emission lines at maximum and a typical plateau evolution of about 100 days (Phillips et al. 1990).

On the other hand, since the discovery a new kind of SN with spectral features similar to those of Seyfert 1 nuclei (Filippenko 1989), there has been a wide record of new events in SN catalogues, and a body of studies that highlight their exceptional characteristics. The new SN group, named SN IIn (Schlegel 1990, Filippenko 1997), show variable broad
emission lines of up to FWHM \( \approx 20000 \text{ km s}^{-1} \), sitting below prominent narrow emission lines (hence the ‘n’), and a light decay much flatter than typical SN. The absence of the characteristic P-Cygni profiles of expanding atmospheres throughout their evolution is remarkable. Some of these SN IIn are exceptionally bright at radio, optical and X-ray wavelengths, with total radiated energies of several times \( 10^{51} \text{ erg} \) in less than a decade (Aretxaga et al. 1999), i.e. two orders of magnitude more than typical SN events. These properties have been interpreted in the light of quick reprocessing of the kinetical energy released in the explosion by a dense circumstellar medium (Chugai 1991, Terlevich et al. 1992), and thus explain the phenomenon as a young and compact supernova remnant (cSNR) rather than a SN.

There is little doubt that if a SN IIn explodes in the center of a normal galaxy, the nucleus would be classified as a Seyfert 1, while the prominent broad lines remain visible. In fact, there has been a succession of theoretical works that explain the phenomenology of lines and continuum at UV to near-IR wavelengths in Seyfert 1 nuclei in terms of a starburst that undergoes SN IIn explosions (e.g. Terlevich et al. 1992, 1995, Aretxaga & Terlevich 1994).

Figure 2 plots the evolution of the H\( \alpha \) line width and luminosity as a function of time compared with the values found in one of the best followed-up SN IIn SN 1988Z (data from Aretxaga et al. 1999), and the H\( \beta \) luminosity evolution of the Seyfert 1 NGC 5548 (data from Korista et al. 1995). The time axis for the comparison is uncertain. We have opted to match the light curves of SN 1988Z, NGC 7582 and NGC 5548 at the maximum light. This also matches the minimum in the light evolution of NGC 5548 as the onset of the 'elementary unit of variation' in Seyfert 1 nuclei proposed by Cid Fernandes, Terlevich & Aretxaga (1997). All fluxes have been normalized to the maximum value. The line-width evolution of NGC 7582 closely resembles the early evolution of SN 1988Z, but the early
evolution of the line intensity seems much steeper than that experienced by SN 1988Z or NGC 5548.

A close multi-wavelength monitoring of this object is thus required if we want to elucidate the mechanism that has created the broad-lines despite the supposedly still existing thick torus that blocks the inner nuclear region from the line of sight. In particular it would be interesting to check if the evolution of the flare experienced by NGC 7582 shows a behaviour similar to SN 1988Z or NGC 5548 (common to other Seyfert 1), represented in Figure 2. This does not necessarily be the case if the variation is driven by a change in the column of obscuring material that crosses our line of sight.

Acknowledgments

We would like to thank the ESO-La Silla staff and particularly J. Brewer and F. Patat for their diligent and efficient help, and I.M. Hook who shared with us part of her allocated observing time. We are indebted to G. Tenorio-Tagle and M. Mas-Hesse for very useful discussions and suggestions on an early draft of this paper.
