(Dated: February 1, 2008)

We investigate the performances of a selective cloning machine based on linear optical elements and Gaussian measurements, which allows to clone at will one of the two incoming input states. This machine is a complete generalization of a 1 → 2 cloning scheme demonstrated by U. L. Andersen et al. [Phys. Rev. Lett. 94, 240503 (2005)]. The input-output fidelity is studied for generic Gaussian input state and the effect of non-unit quantum efficiency is also taken into account. We show that if the states to be cloned are squeezed states with known squeezing parameter, then the fidelity can be enhanced using a third suitable squeezed state during the final stage of the cloning process. A binary communication protocol based on the selective cloning machine is also discussed.

I. INTRODUCTION

Basic laws of quantum mechanics do not allow the generation of exactly alike copies of an unknown quantum state [1, 2, 3, 4]. However, approximate copies can be obtained by using devices called quantum cloning machine [5]. The first of such devices was studied to deal with qubits and then a continuous variable (CV) [6] analog was developed [7, 8]. Thereafter, CV optimal Gaussian clones of coherent states based on two quite different approaches were proposed: the one relies on a single phase insensitive parametric amplifier [9, 10], the other, which has been also experimentally realized, is built around a feed-forward loop [11]. On the other hand, the latter is much simpler than the first one, overcoming the difficulty of implementing an efficient phase insensitive amplifier operating at the fundamental limit. Since the setup of this device is based only on linear components, throughout this paper we’ll refer to it as linear cloning machine. Ref. [12] investigated the performances of the linear cloning machine when the input state was a single generic Gaussian state (coherent, squeezed coherent or displaced thermal state) taking into account the effect of fluctuation of the input state covariance matrix, variation in the setups beam splitter ratios and losses in the detection scheme.

The aim of this paper is to show that the protocol used by the linear cloning machine to clone a single input Gaussian state can be generalized in order achieve the selective cloning a state chosen between two inputs. The possibility to select one of two states may have useful implementation in binary communication systems where the two bits are encoded in two quantum states and the goal of the communication is to sent the information from one sender to two receivers. We’ll address this problem in the final part of the paper.

The paper is structured as follows: in Sec. I we describe the selective cloning machine and describe the evolution of the input states by means of the characteristic function approach. In Sec. III the requirements of selective symmetric cloning are exploited and the input-output fidelity is studied. Sec. IV investigate the possibility to enhance the cloning fidelity and in Sec. V a possible application of the selective cloning machine to 1 → 2 binary communication is proposed. Finally, Sec. VI closes the paper with some concluding remarks.

II. THE SELECTIVE LINEAR CLONING MACHINE

The selective cloning machine based on linear optics and Gaussian measurement is schematically depicted in Fig. 1. Two input states, denoted by the density operators $\rho_k$, $k = 1, 2$, are mixed at a beam splitter (BS) with transmissivity $\tau_1$. One of the two emerging beams is measured by a measurement described by the POVM $\Pi_k(z)$ and the outcome $z$ is forwarded to a modulator, which imposes a displacement $gz$ on the other outgoing beam, $g$ being a suitable amplification factor. Finally, the displaced state is mixed with the state $\rho_3$ at second beam splitter of transmissivity $\tau_2$. The two outputs, $\varsigma_1$ and $\varsigma_2$, from the beam splitter represents the two clones, which may be made approximately equal to either $\varsigma_1$ or $\varsigma_2$ by changing the gain $g$ from +1 to −1.

FIG. 1: Selective cloning of Gaussian states by linear optics: the two input states $\rho_k$, $k = 1, 2$, are mixed at a beam splitter (BS) of transmissivity $\tau_1$. One of the two emerging beams is measured by a measurement described by the POVM $\Pi_k(z)$ and the outcome $z$ is forwarded to a modulator, which imposes a displacement $gz$ on the other outgoing beam, $g$ being a suitable amplification factor. Finally, the displaced state is mixed with the state $\rho_3$ at second beam splitter of transmissivity $\tau_2$. The two outputs, $\varsigma_1$ and $\varsigma_2$, from the beam splitter represents the two clones, which may be made approximately equal to either $\varsigma_1$ or $\varsigma_2$ by changing the gain $g$ from +1 to −1.
placed state using another BS with transmissivity $\tau_2$. When $\tau_1 = \tau_2 = 1/2$, $g = 1$, $\eta = 1$, $\varrho_2 = \varrho_3 = |0\rangle\langle 0|$ and the Gaussian measurement is an ideal double homodyne detection the scheme reduces to that of Ref. [11], which was shown to be optimal for Gaussian cloning of coherent states and has been investigated in Refs. [12, 13, 14]. In the following we carry out a thorough description of the selective cloning machine using the characteristic function approach.

The characteristic function $\chi_k(\Lambda_k) \equiv \chi[\varrho_k](\Lambda_k)$ associated with a Gaussian state $\varrho_k$ of mode $k = 1, 2, 3$ (see Fig. 1) reads:

$$\chi_k(\Lambda_k) = \exp \left\{ -\frac{i}{2} \Lambda_k^T \sigma_k \Lambda_k - i \Lambda_k^T X_k \right\},$$

(1)

where $\Lambda_k = (x_k, y_k)^T$, $\cdots )^T$ denotes the transposition operation, $\sigma_k$ is the covariance matrix, and $X_k = \text{Tr}[\varrho_k (\hat{x}, \hat{y})^T]$ is the vector of mean values, $\hat{x}$ and $\hat{y}$ being the quadrature operators $\hat{x} = \frac{1}{\sqrt{2}}(\hat{a} + \hat{a}^\dagger)$ and $\hat{y} = \frac{i}{\sqrt{2}}(\hat{a} - \hat{a}^\dagger)$, with $\hat{a}$ and $\hat{a}^\dagger$ being the field annihilation and creation operator. In turn, the initial two-mode state $\varrho = \varrho_1 \otimes \varrho_2$ is Gaussian and its two-mode characteristic function reads:

$$\chi[\varrho](\Lambda) = \exp \left\{ -\frac{i}{2} \Lambda^T \sigma \Lambda - i \Lambda^T X \right\},$$

(2)

with

$$\sigma = \begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{pmatrix}, \quad X = (X_1, X_2)^T,$$

(3)

and $\Lambda = (\Lambda_1, \Lambda_2)$. Under the action of the first BS the state $\chi[\varrho](\Lambda)$ preserves its Gaussian form, namely

$$\chi[\varrho](\Lambda) \Rightarrow \chi[\varrho'](\Lambda) = \exp \left\{ -\frac{i}{2} \Lambda^T \sigma \Lambda - i \Lambda^T X \right\},$$

(4)

where $\varrho' = U_{BS,1} \varrho_1 \otimes \varrho_2 U_{BS,1}^\dagger$, while its covariance matrix and mean values transform as [15]:

$$\sigma \Rightarrow \tilde{\sigma} \equiv S_{BS,1}^T \sigma S_{BS,1} = \begin{pmatrix} A & C \\ C^T & B \end{pmatrix},$$

(5)

$$X \Rightarrow \tilde{X} \equiv S_{BS,1}^T X = (\tilde{X}_1, \tilde{X}_2)^T,$$

(6)

$$A, B, \text{and } C \text{ are } 2 \times 2 \text{ matrices, and }$$

$$S_{BS,1} = \begin{pmatrix} \sqrt{\tau_1} & 1/2 \\ -\sqrt{1-\tau_1} & 1/2 \end{pmatrix},$$

(7)

is the symplectic transformation associated with the evolution operator $U_{BS,1}$ of the BS with transmission $\tau_1$. Note that $\varrho'$ is an entangled state if the set of states to be cloned consists of non-classical states, i.e., states with singular Glauber P-function or negative Wigner function [16, 17].

The Gaussian measurement with quantum efficiency $\eta$ (see Fig. 1) is described by the characteristic function

$$\chi[\Pi_\eta(z)](\Lambda_2) = \frac{1}{\pi} \exp \left\{ -\frac{i}{2} \Lambda_2^T \sigma_M \Lambda_2 - i \Lambda_2^T X_M \right\},$$

(8)

with $X_M = \sqrt{2} (\text{Re}[z], \text{Im}[z])^T$ and $\sigma_M \equiv \sigma_M(\eta)$. The probability of obtaining the outcome $z$ is then given by

$$p_\eta(z) = \text{Tr}_{12}[\varrho' \otimes \Pi_\eta(z)]$$

(9)

$$= \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} d^4A \chi[\varrho'](A) \chi[\Pi_\eta(z)](-A)$$

(10)

$$= \exp \left\{ -\frac{i}{2} \left( X_M - \tilde{X}_2 \right)^T \Sigma^{-1} \left( X_M - \tilde{X}_2 \right) \right\},$$

(11)

where $\chi[\Pi \otimes \Pi_\eta(z)](\Lambda) \equiv \chi[\Pi](\Lambda_1) \chi[\Pi_\eta(z)](\Lambda_2)$, $\chi[\Pi](\Lambda_1) = 2\pi \delta^{(2)}(\Lambda_1)$ and $\delta^{(2)}(\zeta)$ is the complex Dirac’s delta function. We also introduced the $2 \times 2$ matrix $\Sigma = B + \sigma_M$.

The conditional state $\varrho_c$ of the other outgoing beam, obtained when the outcome of the measurement is $z$, i.e.,

$$\varrho_c = \frac{\text{Tr}_2[\varrho' \Pi_\eta(z)]}{p_\eta(z)},$$

(12)

has the following characteristic function (for the sake of clarity we explicitly write the dependence on $\Lambda_1$ and $\Lambda_2$):

$$\chi[\varrho_c](\Lambda_1) = \int_{\mathbb{R}^2} d^2A_2 \chi[\varrho'](A_1, A_2) \chi[\Pi_\eta(z)](\Lambda_2)$$

(13)

$$= \exp \left\{ -\frac{i}{2} \Lambda_1^T \left[ A - C \Sigma^{-1} C^T \right] A_1 \right\}$$

$$- i \Lambda_1^T \left[ C \Sigma^{-1} (X_M - \tilde{X}_2) + \tilde{X}_1 \right]\right\}.$$
respectively, which, as in the case of Eqs. (5) and (6), under the action of the BS transform as follows:

$$ \sigma_1 \rightarrow \sigma_{\text{out}} \equiv S^T_{\text{BS,2}} \sigma_1 S_{\text{BS,2}} = \left( \begin{array}{cc} \mathcal{A} & \mathcal{C} \\ \mathcal{C}^T & \mathcal{A} \end{array} \right), \quad (18) $$

$$ X_1 \rightarrow X_{\text{out}} = S^T_{\text{BS,2}} X_1 = (X_1, X_2)^T, \quad (19) $$

where $\mathcal{A}$ and $\mathcal{C}$ are $2 \times 2$ matrices, and $S_{\text{BS,2}}$ is the symplectic matrix given by Eq. (7) with $\tau_1$ replaced by $\tau_2$. Finally, the (Gaussian) characteristic function of the clone $\varsigma_k$, $k = 1, 2$, is obtained by integrating over $\Lambda_{k, h} \neq k$, the two-mode characteristic function $\chi(\rho_{\text{out}})(\Lambda_1, \Lambda_2)$, where $\rho_{\text{out}} = U_{\text{BS,2}} \rho_1 \otimes \rho_3 U^T_{\text{BS,2}}$, i.e.,

$$ \chi(\varsigma_k)(\Lambda_k) = \frac{1}{2\pi} \int_{\mathbb{R}^2} d^2\Lambda_k \chi(\rho_{\text{out}})(\Lambda_1, \Lambda_2) = \exp \left\{ -\frac{1}{2} \mathcal{A}_k^T \mathcal{A}_k \varsigma_k - i\mathcal{A}_k^T \mathcal{F}_k \right\}. \quad (21) $$

The explicit expressions of $\mathcal{X}_1$ and $\mathcal{X}_2$ are

$$ \mathcal{X}_1 = \sqrt{\tau_2} \left( f_1 X_1 + f_2 X_2 \right) - \sqrt{1 - \tau_2} X_3, \quad (22a) $$

$$ \mathcal{X}_2 = \sqrt{1 - \tau_2} \left( f_1 X_1 + f_2 X_2 \right) + \sqrt{\tau_2} X_3, \quad (22b) $$

with

$$ f_1 \equiv f_1(\tau_1, \tau_2, g) = \sqrt{\tau_1} + g \sqrt{1 - \tau_1}, \quad (23) $$

$$ f_2 \equiv f_2(\tau_1, \tau_2, g) = g \sqrt{\tau_1} - \sqrt{1 - \tau_1}, \quad (24) $$

whereas, $\mathcal{X}_1$ and $\mathcal{X}_2$ can be written in a compact form as follows:

$$ \mathcal{X}_1 = \tau_2 \left( f_1^2 \sigma_1 + f_2^2 \sigma_2 + g^2 \sigma_M \right) + (1 - \tau_2) \sigma_3, \quad (25a) $$

$$ \mathcal{X}_2 = (1 - \tau_2) \left( f_1^2 \sigma_1 + f_2^2 \sigma_2 + g^2 \sigma_M \right) + \tau_2 \sigma_3. \quad (25b) $$

### III. SELECTIVE CLONING

From Eqs. (22) and (25) we see that the two outgoing states $\varsigma_1$ and $\varsigma_2$ are generally different. In this paper we’ll consider in detail the case in which the clones are equal, therefore, in order to make them exactly alike, one have to put $\tau_2 = 1/2$ and $X_3 = 0$: in this case, $\mathcal{X}_1 = \mathcal{X}_2$ and $\mathcal{X}_1 = \mathcal{X}_2$. A further inspection of Eqs. (22) and (25) with $\tau_2 = 1/2$, shows that the states $\varsigma_k$ could be quite different from both the input states, being the covariance matrices and the mean values vectors a linear combination of the input ones. On the other hand, if $f_2$ (or $f_1$) vanishes, then the Gaussian output states depend only on $\sigma_1$, $X_1$ (or $\sigma_2$, $X_2$), $\sigma_3$ and $\sigma_M$. In the following we’ll investigate thoroughly this scenario.

After we have chosen the symmetric outputs setup, i.e., $\tau_2 = 1/2$ and $X_3 = 0$, we are interested in removing the dependence on the state, e.g., $\varsigma_2$ from the output states, namely, we want to let $f_2$ vanish; this is achieved when

$$ g \equiv g_1(\tau_1) = \sqrt{(1 - \tau_1)/\tau_1}, \quad (26) $$

| $g$ | $\varsigma_1 = \varsigma_2$ | $\mathcal{X}_1 = \mathcal{X}_2$ |
|-----|-----------------|-----------------|
| 1   | $\sigma_1 + \frac{1}{2} (\sigma_3 + \sigma_M)$ | $X_1$ |
| -1  | $\sigma_2 + \frac{1}{2} (\sigma_3 + \sigma_M)$ | $-X_2$ |

which gives $f_1 = \tau_1^{-1/2}$ and leads to

$$ \mathcal{X}_1 = \mathcal{X}_2 = (2\tau_1)^{-1/2} X_1, \quad (27) $$

$$ \varsigma_1 = \varsigma_2 = \frac{1}{2} \left[ 1 - \frac{\sigma_1 + \sigma_3 + \tau_1 \sigma_M}{1 - \tau_1} \right]. \quad (28) $$

It is now clear that if the first BS is balanced ($\tau_1 = 1/2$), we obtain

$$ \mathcal{X}_1 = \mathcal{X}_2 = X_1, \quad (29a) $$

$$ \varsigma_1 = \varsigma_2 = \sigma_1 + \frac{1}{2} (\sigma_3 + \sigma_M). \quad (29b) $$

This is the $1 \rightarrow 2$ symmetric cloning of the state $\varsigma_1$. This configuration has been experimentally implemented to optimally clone coherent states [11, 12]. Notice that $g_1(1/2) = 1$.

On the contrary, in order to eliminate the dependence on the state $\varsigma_1$ one needs (we are assuming again $\tau_2 = 1/2$ and $X_3 = 0$):

$$ g \equiv g_2(\tau_1) = -\sqrt{\tau_1/(1 - \tau_1)}, \quad (30) $$

which gives $f_2 = -(1 - \tau_1)^{-1/2}$ and leads to

$$ \mathcal{X}_1 = \mathcal{X}_2 = -[2(1 - \tau_1)]^{-1/2} X_2, \quad (31) $$

$$ \varsigma_1 = \varsigma_2 = \frac{1}{2} \left[ 1 - \frac{\sigma_1 + \sigma_3 + \tau_1}{1 - \tau_1} \sigma_M \right], \quad (32) $$

and if $\tau_1 = 1/2$ one has

$$ \mathcal{X}_1 = \mathcal{X}_2 = -X_2, \quad (33a) $$

$$ \varsigma_1 = \varsigma_2 = \sigma_2 + \frac{1}{2} (\sigma_3 + \sigma_M). \quad (33b) $$

As a matter of fact, to obtain the actual symmetric cloning of the state $\varsigma_1$ we have to implement a unitary transformation to change the phase of the output states as follows: $\mathcal{X}_h \rightarrow -\mathcal{X}_h$. Notice that $g_2(1/2) = -1$.

The results of this Section are summarized in Table I in the case of symmetric cloning ($\tau_1 = \tau_2 = 1/2$ and $X_3 = 0$), one can select the state to clone simply change the value of the gain $g$ from +1 to -1.

### IV. ENHANCEMENT OF LINEAR CLONING FIDELITY

The similarity between the input state $\varrho_k$ and the clone $\varsigma_k$, $k, h = 1, 2$, can be quantified by means of the fidelity [13]

$$ F(\varrho_k, \varsigma_h) = \left( \text{Tr} \sqrt{\varrho_k \varsigma_h \varrho_k} \right)^2, \quad (34) $$
which, for Gaussian states, reduces to \[12, 13, 20\]

\[
F_\eta = \frac{1}{\sqrt{\det[(\sigma_k + \omega_k)]}} \times \exp \left\{ -\frac{1}{2} (X_k - \mathcal{F}_h)^T (\sigma_k + \omega_k)^{-1} (X_k - \mathcal{F}_h) \right\},
\]

where \( \delta = 4(\det[\sigma_k] - \frac{1}{2})/(\det[\omega_k] - \frac{1}{2}) \). Note that for pure Gaussian states \( \det[\sigma_k] = \frac{1}{4} \), and in turn \( \delta = 0 \). In the case of symmetric cloning \( X_k = \mathcal{F}_h \), the fidelity \[35\] reduces to

\[
F_\eta(\sigma_k, \sigma_M) \equiv \frac{1}{\sqrt{\det[(\sigma_k + \omega_M)]}} \times \exp \left\{ -\frac{1}{2} (X_k - \mathcal{F}_h)^T (\sigma_k + \omega_M)^{-1} (X_k - \mathcal{F}_h) \right\},
\]

and the cloning machine is said to be universal because of its invariance with respect to displacement of the input states.

It is a matter of fact that we can now maximize Eq. \[36\] by a suitable choice of the state \( \varrho_3 \) \( (\sigma_1, \sigma_3, \text{and } \sigma_M \text{ being fixed}) \). Without loss of generality we assume that the covariance matrix associated with \( \varrho_3 \) has the following diagonal form

\[
\sigma_3 = \begin{pmatrix}
\omega_{11} & 0 \\
0 & \omega_{22}
\end{pmatrix}
\]

(37)

with

\[
\omega_{11} = \frac{2 + 1}{2} e^{2s}, \quad \omega_{22} = \frac{2 + 1}{2} e^{-2s},
\]

(38)

i.e., a squeezed thermal state with \( \mathcal{F} \) mean thermal photons and squeezed parameter \( s \). We recall that \( X_3 = 0 \) in order to fulfill the symmetric cloning requirements. Now, if

\[
\sigma_k = \begin{pmatrix}
\gamma_{11} & \gamma_{12} \\
\gamma_{12} & \gamma_{22}
\end{pmatrix}, \quad \sigma_M = \begin{pmatrix}
\Delta_{11} & \Delta_{12} \\
\Delta_{12} & \Delta_{22}
\end{pmatrix},
\]

(39)

are the explicit forms of the covariance matrices of \( \varrho_k \), \( k = 1, 2, \) and of the measurement \( \Pi_M(z) \), respectively, then we find that the fidelity reaches the maximum for (for the sake of simplicity we do not report explicitly the dependence of \( \gamma_{mn} \) on \( k \), being clear what is the input state \( \varrho_3 \) under consideration)

\[
s = \pi \equiv \frac{1}{4} \log \left( \frac{4\gamma_{11} + \Delta_{11}^2}{4\gamma_{22} + \Delta_{22}^2} \right), \quad \mathcal{F} = 0,
\]

(40)

i.e., \( \varrho_3 \) should be a squeezed vacuum state with covariance matrix \( \sigma_3 \equiv \sigma_r = \frac{1}{2} \text{Diag}(e^{2\sigma}, e^{-2\sigma}) \). Indeed, such a maximization of the fidelity requires the knowledge of \( \gamma_{11} \) and \( \gamma_{22} \).

The result obtained above generalizes the conclusions given in Ref. \[12\]. The linear cloning machine described in \[12\], used to perform \( 1 \rightarrow 2 \) cloning of the state \( \varrho_1 \), follows from the present scheme choosing \( \varrho_3 \equiv \varrho_3 = |0\rangle\langle 0| \), corresponding to \( \sigma_1 = \sigma_3 = \sigma_0 \equiv \frac{1}{2} I_2 \), and \( \sigma_M = \frac{2 - r^2}{2r} I_2 \), which describes the covariance matrix of the double homodyne detection with quantum efficiency \( \eta \). From Eq. \[40\] we see that sending the vacuum into the second BS is the best choice only if \( \varrho_1 \) is a coherent state or a displaced thermal state \[12\] (in both the cases \( s = 0 \) and \( \sigma_3 \) reduces to the vacuum state covariance matrix being \( X_3 = 0 \)). On the contrary, when \( \sigma_k \) is the covariance matrix associated with the squeezed state \( D(\alpha) S(r)|0\rangle = |\alpha, r\rangle \), where \( D(\alpha) = \exp\{\alpha a^\dagger - \alpha^* a\} \) and \( S(r) = \exp\{\frac{1}{2} r^2 (a^2 - a^\dagger)^2\} \) are the displacement and squeezing operators, respectively, \( r \) being the real squeezing parameter, then \( 2\gamma_{11} = 2\gamma_{22} = e^{2r} \) and the cloning fidelity is optimized if \( \varrho_3 \) is a squeezed state with squeezing parameter given by Eq. \[40\]. Fig. 2 shows the enhancement of the fidelity in the case of squeezed state 1 \( \rightarrow \) 2 cloning when a suitable squeezed vacuum state with squeezing parameter \( \pi \) given in Eq. \[40\] is used instead of the vacuum state as input \( \varrho_3 \) (see Fig. 1). The effect of non-unit quantum efficiency can be seen in Fig. 3 where we plot the quantity

\[
G(r, \eta) = \frac{F_\eta(\sigma_1, \sigma_M) - F_\eta(\sigma_1, \sigma_0, \sigma_M)}{F_\eta(\sigma_1, \sigma_0, \sigma_M)},
\]

(41)

as a function of \( r \) for different values of \( \eta \). \( G(r, \eta) \) expresses the relative improvement of cloning fidelity. As it is apparent from the plot, one has enhancement of fidelity for any value of \( \eta \) as far as the signals show nonzero squeezing.
In this Section we address an application of the selective cloning machine to a 1 → 2 binary communication protocol. The goal is to encode a classical sequence (string) $S$ of two classical symbols, e.g., “−1” and “+1”, into a quantum sequence $S'$ of two quantum states, e.g., $\varrho_1$ and $\varrho_2$, eventually unknown, and to send it to two receivers, which are interested not only in the classical message but also in the quantum states encoding it. In this case a cloning machine is necessary to generate the copies $R_1$ and $R_2$ of $S'$. Let us now assume that the sender, which possesses the string $S$, is not able to generate $S'$ itself, so he needs a service provider that provides a communication channel based on the states $\varrho_1$ and $\varrho_2$. However, since the service provider does not know $S$, the communication channel should be independent on the message the sender want to send. In this scenario the selective cloning machine (operating in the symmetric cloning regime) presented above can be a useful tool.

The 1 → 2 communication protocol based on the selective cloning machine is sketched in Fig. 4 and can be summarized in these steps:

- the service provider mixes $\varrho_1$ and $\varrho_2$ at the balanced BS and addresses the outputs to the sender;
- the sender performs the double homodyne detection onto one of the two beams and displaces the other one by an amount $g z$, $z$ being the outcome of the measurement and $g$ being chosen according to the bits 1 or 0;
- the displaced beam is divided into the two clones $\tilde{\varsigma}_1(z) = \tilde{\varsigma}_2(z) = \tilde{\varsigma}^{(k)}(z)$ by means of another balanced BS, with $k = 1 (k = 2)$ if $g = +1 (g = -1)$.

It is worth noting that the selective cloning machine is now operating at a “single shot” regime, namely, each clone is obtained after a single outcome $z$ of the double homodyne detection and not after a complete measurement onto a state. In turn, each clone actually depends on $z$. Once the receivers get the single clone, they need a strategy to decide if the bit was +1, corresponding to $\varrho_1$, or −1, corresponding to $\varrho_2$.

In order to illustrate the protocol, in the following we address the simple case in which

$$\varrho_1 = \varrho_2 = |\alpha\rangle\langle\alpha|, \tag{42}$$

are coherent states, i.e., $\sigma_k = \frac{1}{\sqrt{2}}|1\rangle\langle 1|$ and $X_1 = X_2 = \sqrt{2}\alpha$ (for the sake of simplicity we take $\alpha$ as real and positive). We recall that the clones of $\varrho_2$ have the amplitude with a $\pi$ phase shift (see Table 2) with respect to input one: in this way it is possible to distinguish between $\tilde{\varsigma}^{(1)}(z)$ and $\tilde{\varsigma}^{(2)}(z)$. Note that one has

$$U_{BS,1} \varrho_1 \otimes \varrho_2 U_{BS,1}^\dagger = |00\rangle\langle 00| \otimes |\sqrt{2}\alpha\rangle\langle \sqrt{2}\alpha|, \tag{43}$$

One of the possible strategies to distinguish between $\varsigma^{(1)}(z)$ and $\varsigma^{(2)}(z)$ is performing a homodyne detection, which is described by the POVM [21]

$$\Pi_x(\varepsilon) = \frac{1}{\sqrt{2}\pi \sigma_z^2} \int_{-\infty}^{\infty} dy \exp \left\{ -\frac{(y-x)^2}{2\sigma_z^2} \right\} \Pi_y, \tag{44}$$

where $\sigma_z^2 = (1 - \varepsilon)/(4\varepsilon)$, $\varepsilon$ is the detection quantum efficiency, and $\Pi_y = |y\rangle\langle y|$, with

$$|y\rangle = \frac{e^{-y^2/2}}{\pi^{1/4}} \sum_{n=0}^{\infty} \frac{H_n(y)}{\sqrt{n!2^n}} |n\rangle \tag{45}$$

being an eigenstate of the quadrature operator $\hat{y} = \frac{1}{\sqrt{2}}(\alpha + \alpha^\dagger)$ of the measured mode. In equation (45) $H_n(y)$ denotes the $n$-th Hermite polynomials. Finally, the decision is taken according to the following rule: if $x \geq \pi \Rightarrow k = 1$, otherwise $k = 2$, $\pi$ being a threshold value. On the other hand, $\varsigma^{(1)}(z)$ and $\varsigma^{(2)}(z)$ are not orthogonal, and then we have to evaluate the probability to infer the wrong state, namely, the error probability defined as follows:

$$H_e(z) = \frac{1}{2} \left[ P_z(2|1) + P_z(1|2) \right], \tag{46}$$

where $P_z(h|k)$ is the probability to infer the state $\tilde{\varsigma}^{(h)}(z)$ when the actual state was $\tilde{\varsigma}^{(k)}(z)$, $h \neq k$. In writing Eq. (46) we assumed that the two states are sent with the same a priori probability $p = 1/2$. The explicit expressions of $P_z(2|1)$ and $P_z(1|2)$ read as follows:

$$P_z(2|1) = \int_{-\infty}^{\pi} dx \text{Tr} \left[ \varsigma^{(1)}(z) \Pi_x(\varepsilon) \right], \tag{47a}$$

$$P_z(1|2) = \int_{-\pi}^{\infty} dx \text{Tr} \left[ \varsigma^{(2)}(z) \Pi_x(\varepsilon) \right]. \tag{47b}$$

It is easy to see that because of the choice of the states $\varrho_1$ and $\varrho_2$, the probability $H_e(z)$ is minimum when $\pi = 0$. The average error probability is then given by

$$\overline{H}_e(\alpha, \eta, \varepsilon) = \int \frac{d^2z}{C} \rho_0(z) H_e(z), \tag{48}$$
We plot Eq. (25) as a function of the amplitude $\alpha$ and different values of the quantum efficiencies: we set $\varepsilon = 1.0$ and, from bottom to top, $\eta = 1.0, 0.5, \text{ and } 0.75$.

We have addressed the performances of $1 \rightarrow 2$ selective cloning machine based on linear optics and Gaussian measurement, which allows to clone one of two incoming input states. We have shown that this is achieved simply changing the gain of a feed-forward loop. Moreover a third Gaussian state can be used in the final stage of the cloning process in order to enhance the input-output fidelity. We have found that for coherent or thermal states this state reduces to the vacuum state, whereas a vacuum squeezed state depending on the squeezing parameter of the inputs and on the measurement should be considered when the states to be cloned are squeezed states. Finally, a protocol for $1 \rightarrow 2$ binary communication involving the selective cloning machine has been proposed and the average error probability has been evaluated for a particular choice of the involved states.

VI. CONCLUDING REMARKS

We have addressed the performances of $1 \rightarrow 2$ selective cloning machine based on linear optics and Gaussian measurement, which allows to clone one of two incoming input states. We have shown that this is achieved simply changing the gain of a feed-forward loop. Moreover a third Gaussian state can be used in the final stage of the cloning process in order to enhance the input-output fidelity. We have found that for coherent or thermal states this state reduces to the vacuum state, whereas a vacuum squeezed state depending on the squeezing parameter of the inputs and on the measurement should be considered when the states to be cloned are squeezed states. Finally, a protocol for $1 \rightarrow 2$ binary communication involving the selective cloning machine has been proposed and the average error probability has been evaluated for a particular choice of the involved states.
