ABSTRACT

We have observed four massive galaxy clusters with the SPIRE instrument on the Herschel Space Observatory and measure a deficit of surface brightness within their central region after removing detected sources. We simulate the effects of instrumental sensitivity and resolution, the source population, and the lensing effect of the clusters to estimate the shape and amplitude of the deficit. The amplitude of the central deficit is a strong function of the surface density and flux distribution of the background sources. We find that for the current best fitting faint end number counts, and excellent lensing models, the most likely amplitude of the central deficit is the full intensity of the cosmic infrared background (CIB). Our measurement leads to a lower limit to the integrated total intensity of the CIB of $I_{250 \mu m} > 0.69_{-0.03}^{+0.03}$ (stat.)$^{+0.06}_{-0.06}$ (sys.) MJy sr$^{-1}$, with more CIB possible from both low-redshift sources and from sources within the target clusters. It should be possible to observe this effect in existing high angular resolution data at other wavelengths where the CIB is bright, which would allow tests of models of the faint source component of the CIB.

Subject headings: cosmic background radiation

1. INTRODUCTION

The effect of gravitational lensing is to redistribute the intensity from sources behind the lens into images with different positions and brightnesses, while conserving surface brightness [Schneider et al. 1992]. This means that gravitational lensing not only magnifies the background sources, but also changes their apparent density on the sky. The details of whether the number counts of background sources seen through a foreground gravitational lens are increased or decreased depend on the properties of the lens and the slope of the faint counts [Refregier & Loeb 1997], a process known as magnification bias [Turner 1980].

In this Letter, we report detection of a deficit in the surface brightness of the cosmic infrared background (CIB) in the centers of massive galaxy clusters measured using the SPIRE instrument [Griffin et al. 2010] on the Herschel Space Observatory [Pilbratt et al. 2010]. To interpret these observations and understand the consequences of lensing a background field, the lensing properties of the cluster and the background source population are carefully simulated in a large number of realizations. We concentrate on the intensity profile after removing detected sources to highlight faint fluctuations in the CIB. The resulting effect after such a removal is a localized region of decreased surface brightness at the cluster center. We use these observations to constrain the intensity of the submillimeter (sub-mm) background at 250 µm.

2. OBSERVATION OF THE DEFICIT

This study uses confusion-limited maps of galaxy clusters from the Herschel, Multi-tiered Extragalactic Survey (HerMES; HerMES Collaboration et al. 2012). The SPIRE data are reduced using a combination of the HIPE (Ott et al. 2006) and SFL (Levenson et al. 2010; Viero et al. 2012) packages. The sample of clusters is listed in HerMES Collaboration et al. (2012) and M. Zemcov et al. (in preparation).

In order to study the strongly lensed regions it is necessary to restrict our attention to those clusters large enough that $\Omega_c > 3\Omega_L$, where $\Omega_c$ is the solid angle of the negative magnification region and $\Omega_L$ is the solid angle of the SPIRE beam. This cut leaves only four clusters from the HerMES sample of twelve: A370, A1689, A2219 and RX J1347−1145. The negative magnification region in the image plane maps to the interior of the lens caustic in the source plane, so it is a reasonable tracer of the area which undergoes strong lensing. The mapping from total mass to lensing characteristics is complex and the area $\Omega_c$ is not strictly proportional to cluster mass; however, this cut does effectively restrict our analysis to the most massive centrally condensed systems.

To measure the deficit, a catalog is generated for each cluster at each SPIRE wavelength using the scat algorithm (Smith et al. 2012) based on 250$\mu$m source selection. Our goal is not to identify particular point sources, but rather to remove emission from bright point sources, so employing a low detection threshold is reasonable. We chose a 1$\sigma$ threshold, where $\sigma$ is the map root-mean-square variation, dominated in these maps by confusion noise. The measurement is not sensitive to the precise value of this number provided it is not so high as to leave residual sources ($> 3\sigma$) nor so low as to needlessly mask a large fraction of the map ($< 0.5\sigma$).

This yields a catalog of $\sim 500$ sources in each cluster field which are then subtracted from the cluster image using a Gaussian model of the beam. An example of the resulting image for one cluster is shown in Figure 1 which shows a statistical deficit in surface brightness near the center of the cluster. A simple way to visualize this deficit is to plot annular averages of the source-subtracted maps, as shown in Figure 2. Similar averages centered on randomly chosen positions in SPIRE images do not show this deficit.

3. THEORETICAL GROUNDS

Gravitational lensing conserves surface brightness and therefore does not alter the mean intensity of the extragalactic background light at any wavelength. However, this statement applies only when all sources are kept in calculating the intensity profile and when averaged over many directions through the cluster – for some configurations of the background sky unusually bright images can be found. The measurement reported here involves the removal of bright detected sources, which leads to a situation where lensing shows a profile that does not conserve intensity. This does not imply that the total number of photons and therefore intensity is not conserved, as discussed in Refregier & Loel (1997), since detected sources are removed.

When viewed through a lensing cluster imposing a magnification $\mu$ on background sources, a background source with flux density $S$ is magnified such that the observed flux density is $S' = \mu S$. The resulting increase in the flux density is accompanied by a corresponding decrease in the projected surface density of galaxies; the observed number density of sources through the lens is modified to be $N' = N/\mu$. The overall effect of this is to modulate existing fluctuations in the background source field. Using the parameterization that the intrinsic number count of the faint background sources scales as $dN/dS \propto S^{-\Gamma}$, the differential number counts lensed through the cluster become $dN'/dS' \propto \mu^{\Gamma-2} S^{-\Gamma}$. The differential counts imaged through the cluster are either decreased or increased depending on whether the intrinsic counts have a slope $\Gamma$ smaller than or greater than 2. If sources are not removed from the image, the total CIB surface brightness is conserved Refregier & Loel (1997).

The observations reported here do not constrain the exact number counts of sources or the difference of the counts of sources through and away from the cluster. One reason for this is that the observations are limited by the angular resolution of the SPIRE instrument, which results in a blending of the faintest sources. The effects of limited-resolution observations of the intensity profile of background sources through the cluster are described in Blain (1997) and Blain (2002). High resolution observations with ALMA will allow more precise measurements of the difference in the counts away from and through the cluster.
redshift planes discretized into $\delta z$ the redshift distribution of the Béthermin et al. (2011) J1347 A2219 – Smith et al. 2005 Richard et al. 2010b; RX – Richard et al. 2010a; A1689 – Limousin et al. 2007; suremestions of strong lensing in the cluster fields (A370 Jullo & Kneib 2009), which are built using optical mea-

tentials of each cluster, including multiple images, gi-

omenology arising from the complex dark-matter po-

4. NUMERICAL SIMULATION

We can use detailed lensing models of these well-

studied clusters and models of the source counts and red-

shift distributions of the sources which comprise the CIB to generate numerical simulations of the observed sky brightness, and explore how the amplitude of an observed deficit depends on source model parameters. To simulate the sub-mm background, we use the model described in Béthermin et al (2011), which is tuned to match a variety of observed number counts $dN/dS$ and is forced to integrate to the total intensity of the CIB Lagache et al. (2000). The model associates both a spectral shape and redshift to each source, down to $z=0$. These simulations do not include coherent clustering of the galaxies which comprise the sub-mm background, which is a small effect on the scales of interest here ($\theta < 3$ arcmin Viero et al. 2012). Poisson noise is modeled by the simulation and accounts for the cosmic variance one would expect in the real sky. The simulated images have area 0.25 deg$^2$ and contain $\sim 5 \times 10^4$ sources to source fluxes $S_{\text{min}} = 50$ nJy.

These simulated backgrounds are then lensed using LENSTOOL models (Kneib et al. 1996 Jullo et al. 2002 Jullo & Kneib 2009), which are built using optical measurements of strong lensing in the cluster fields (A370 – Richard et al. 2010b A1689 – Linsosin et al. 2007 A2219 – Smith et al. 2003 Richard et al. 2010a RX J1347–1145 – Bradac et al. 2008), modeling all of the known high-magnification images measured for each cluster. The LENSTOOL models replicate all of the phenomenology arising from the complex dark-matter potentials of each cluster, including multiple images, giant arcs, etc. Gravitational lensing is achromatic, so the same lens model applies at all wavelengths. Sources with $z < z_c$ are included in the simulated sky map, but are not lensed; all the sources with $z > z_c$ are lensed from redshift planes discretized into $\delta z = 0.1$ steps. Varying the redshift distribution of the Béthermin et al. (2011) model within reasonable limits does not change the results of these simulations. An example of one such simulation is shown in the bottom panels of Figure 4. The central surface brightness deficit is evident in the modeled image in all three SPIRE bands.

These simulations show that three factors contribute to the effect reported here: (1) the sizes and typical lensing amplification factors of clusters, (2) the number densities and redshifts of the sources responsible for the CIB, and (3) the sensitivity and beam size of SPIRE. These combine so that when we examine the lensed cores of SPIRE images of cluster fields and remove all reasonably significant sources, we are left with deficits in the surface brightness of the sky in small regions near the cluster center.

In order to compare the data to the simulations, we use the same procedure discussed above on simulations of the cluster targets. In these simulations, instrumental noise with the same amplitude as the data is inserted into the simulated, lensed cluster images which are propagated through an identical detection/subtraction procedure as the real data, resulting in the gray bands in Figure 2 which represent the mean and standard deviation of the model results drawn from 100 realizations of the background sky. These capture the variance of the lensing deficit due to different background configurations and reflect the range of possible deficit shapes and amplitudes arising from our ignorance of the exact configuration of the background sources.

A potential concern is whether simulating sources to $S \sim 50$ nJy is sufficient for the modeling result to converge. To check this, we have performed simulations where sources are excluded below $S_{\text{min}} = 10$ nJy the map is densely populated and the effect has converged, and including fainter sources does not have an appreciable effect on the amplitude of the deficit. This is because sources below 10 µJy are rarely boosted above the 1$\sigma$ detection threshold so do not create a net deficit.

Figure 2. Intensity profiles towards four clusters, illustrating gravitational lensing of the CIB. The left hand plots show the mean flux density in 0.25-wide annular bins for each cluster after all detected sources have been removed. The central data point is constructed from averaging map pixels within the effective radius characteristic of the clusters’ critical lines (marked by the vertical dashed lines). At larger radii, the data points represent uncertainty-weighted averages starting at the characteristic critical line radius. The mean level of each simulated map is constructed to be zero before source subtraction and is reduced by $\sim 0.3$ MJy sr$^{-1}$ after a large fraction of the CIB has been detected as sources and removed; the offset varies between targets depending on the details of the catalog. The uncertainties on the data points reflect the photometric accuracy of the measurements rather than the precision with which the mean should differ from the model. Dotted lines and grey contours show the model and standard deviation of our sky model, calculated from simulations of the CIB lensed by each cluster and passed through our data analysis pipeline. The right hand plots show the annular averages of the raw cluster images with no source extraction, which highlight the structure of the surface brightness which is subtracted by removing detected sources.
after source removal.

To investigate the dependence of the deficit on the background number counts, we perform simulations drawn from the measured counts presented in Glenn et al. (2010), similar to the calculations in Ford et al. (2012). The slope of the faint end for 0.1 mJy < S < 2 mJy is varied in 1.0 ≤ Γ ≤ 3.0, bracketing the nominal value Γ = 1.65 which accounts for the FIRAS background (Fixsen et al. 1998, Lagache et al. 2000). As can be seen in Figure 3, for shallow slopes, the surface density of sources is small enough to produce zero flux in the center of clusters. For steeper slopes, the probability that a source falls behind the center of the cluster image is no longer small and the surface brightness increases. Existing constraints on the brightness of the CIB at 250 µm exclude Γ > 2.3 at 2σ in this range (Fixsen et al. 1998).

![Figure 3](image)

Figure 3. Effect of the slope of the faint end source counts Γ on the lensing deficit. The surface brightness of the sky is averaged into annular bins centered on the cluster and expressed as a ratio of the brightness at radius r to the overall sky surface brightness. For slopes similar to that inferred from other measurements (Γ ≈ 1.5), the center of our modeled clusters has an expectation value of zero; as the slope is increased, the probability of a source falling into the caustic region is increased until the deficit begins to be filled in.

5. MEASUREMENT OF THE CIB AT 250 MICRONS

According to our simulations using the Béthermin et al. (2011) model, statistically the central region of these clusters’ images have zero surface brightness from lensed sources. At 250 µm, emission from sources within the central arcminute of clusters tends to be faint. Therefore a situation arises where the cluster itself is invisible, the probability of a foreground source coinciding with the cluster center is small, and the background is lensed by the cluster, so no sources of emission exist in the center of the cluster. If this region has zero surface brightness, as the model suggests, we can use it as an absolute zero point.

Of course, if the above assumption is incorrect, any sources of emission local to the cluster center – for example, from the brightest cluster galaxy (BCG) or the Sunyaev-Zeldovich (SZ) effect – will bias the measurement to lower inferred surface brightness. Though only a < 0.1% fractional contamination in the 250 µm SPIRE band, the SZ effect is significant at longer sub-mm wavelengths (Zemcov et al. 2007, Zemcov et al. 2010) so we defer reporting the CIB inferred from the two longer wavelength SPIRE bands to future work. Sub-mm emission associated with the central region of target clusters is known (Rawle et al. 2012); for example, in the HerMES sample (but excluded from this work) Abell 1835 and Abell 2390 are both known to host BCGs with sub-mm fluxes of many mJy. Because of this potential bias, the lensing deficit yields a lower limit to the CIB. To check for contamination from galaxies within the critical region, we use Spitzer-MIPS 24 µm data. No BCGs are obvious in the SPIRE images of the four clusters, but we can use the 24 μm – 250 μm BCG flux density ratio measured by Rawle et al. (2012) to estimate an additional one-sided, positive-going uncertainty to the central zero point in each image. This corresponds to a 1σ value of 0.4 mJy per beam at the position of the BCG. We do not detect other 24 µm sources associated with the cluster in the central deficit region. Diffuse dust emission associated with the intracluster medium has never been detected, but from predictions we expect this kind of emission to be at least an order of magnitude smaller than the surface brightness of the lensing deficit at 250 µm (Popescu et al. 2000).

To determine the absolute intensity of the CIB, the average of each map in its central region is used to generate a zero point for the image. The mean brightness of the resulting image, excluding the central region, is then computed. To estimate the uncertainty associated with each measurement, we compute the quadrature sum of the statistical uncertainty of the maps as traced by the standard deviation of the pixels in the central region (Stat. δI250,µm), the one-sided uncertainty from the BCG emission (BCG δI250,µm), the uncertainty from the simulations associated with the configuration of the background source (Model δI250,µm), and the 5% absolute calibration uncertainty of SPIRE (Abs. Cal. δI250,µm). We estimate the Eddington bias associated with the effect of subtracting sources from the maps before computing the mean of the central region by comparing simulations including and excluding simulated noise, resulting in an estimate of δI < 0.03 MJy sr−1 for the Eddington bias on the sample. Table 1 lists the areas of negative magnification in each target, the inferred CIB brightness for each of the four cluster fields that pass all of the selection cuts, and the uncertainty budget associated with these measurements. The statistical-uncertainty weighted mean of this value, 0.69±0.12 M Jy sr−1, is the inferred brightness of the CIB at 250 µm from the lensing deficit method. This value is consistent with the FIRAS values determined by Puget et al. (1996), Fixsen et al. (1998), and Lagache et al. (2000) in the same band within 1σ.

6. DISCUSSION

We have detected an interesting new phenomenon which is due to the properties of the sub-mm background and gravitational lensing in massive clusters. This deficit in the measured surface brightness constrains the smallest allowable surface brightness of the CIB and so is another way to limit its absolute brightness, adding to a list which includes P(D) analyses, stacking, and source counting, in addition to direct photometric measurement. Furthermore, in principle the presence of this deficit places interesting constraints on the faint end of the number counts, although larger samples and comprehensive modeling are required to convert measurements to source count constraints.

Because gravitational lensing is achromatic, this effect occurs in all of the SPIRE bands. Other instruments
working at sub-mm and mm wavelengths like ACT/SPT and CCAT should also be able to measure this deficit effect, assuming that the background in question is sufficiently far behind the lensing cluster, and that the instrumentation is sensitive to sources at levels similar to SPIRE’s with enough angular resolution to resolve the central region of clusters. In addition, this effect produces a complicated, spatially structured CIB surface brightness distribution which is a potential foreground for high resolution SZ effect measurements at longer wavelengths.

ACKNOWLEDGEMENTS

SPIRE has been developed by a consortium of institutes led by Cardiff Univ. (UK) and including: University of Lethbridge (Canada); NAOC (China); CEA, LAM (France); IFSI, University of Padua (Italy); IAC (Spain); Stockholm Observatory (Sweden); Imperial College London, RAL, UCL-MSSL, UKATC. University of Sussex (UK); Caltech, JPL, NHSC, University of Colorado (USA). This development has been supported by national funding agencies: CSA (Canada); NAOC (China); CEA, CNES, CNRS (France); ASI (Italy); MCINN (Spain); SNSB (Sweden); STFC, UKSA (UK); and NASA (USA).

HCS/HSpot/HiPE are joint developments by the Herschel Science Ground Segment Consortium, consisting of ESA, the NASA Herschel Science Center, and the HIFI, PACS and SPIRE consortia.

This work is based in part on archival data obtained with the Spitzer Space Telescope, which is operated by JPL/Caltech under a contract with NASA.

Support for this work was provided by NASA.
