We characterized 2 clusters of blastomycosis cases in Minnesota, USA, using whole-genome sequencing and single-nucleotide polymorphism analyses. Blastomyces gilchristii was confirmed as the cause of infection. Genomic analyses corresponded with epidemiologic findings for cases of B. gilchristii infections, demonstrating the utility of genomic methods for future blastomycosis outbreak investigations.

Three pathogenic Blastomyces species, B. dermatitidis, B. gilchristii, and B. helicus, have been identified in North America. In the United States, B. dermatisidis has been found throughout areas surrounding the Great Lakes, the Ohio and Mississippi River valleys, and the St. Lawrence River (1). In contrast, B. gilchristii has a smaller geographic range in Canada and the northern United States (2), and B. helicus has been found in the northwestern United States (3). No differences in clinical manifestations have been reported among these Blastomyces species.

In the United States, previous case reports have linked blastomycosis infections to outdoor activities, especially those involving moist soil and proximity to waterways (4,5). One of the largest reported outbreaks of blastomycosis occurred in 2015 among persons who had recreated along the Little Wolf River in Wisconsin (6). In Minnesota, blastomycosis is a reportable disease; epidemiologists at the Minnesota Department of Health (MDH) routinely collect demographic and clinical information for blastomycosis cases and attempt interviews to characterize illness and exposure history. The MDH Public Health Laboratory provides fungal identification services and stores isolates submitted by clinical laboratories.

Although whole-genome sequencing has been used to investigate outbreaks involving various fungal pathogens, such as Candida auris and Coccidioides spp. (7,8), this molecular technology has not been used to investigate Blastomyces spp. outbreaks in the United States. We performed whole-genome sequencing to determine the genetic diversity and phylogenetic relationships of 2 familial clusters of B. gilchristii infections identified in Minnesota.

In August 2020, five cases of blastomycosis were identified as cluster A, which comprised a family of 2 White Hispanic parents and 3 children (Table). Four of the 5 patients were hospitalized, of which 3 had sputum cultures that were positive for Blastomyces sp. All 5 patients recovered from illness. The mother reported that the family had visited rivers in St. Croix County, Wisconsin, numerous times during the summer. No other likely exposure locations or activities were reported.

In addition, 2 cases of blastomycosis were identified in White non-Hispanic sisters. Only 1 sister was hospitalized and had a positive culture for Blastomyces sp. from a bronchoalveolar lavage specimen. MDH learned that their father had blastomycosis in 2014, which was attributed to B. dermatitidis (9). The 2 patients with isolates (1 sister and the father) were classified as cluster B (Table). The family owned a cabin in Hubbard County, Minnesota, which is highly endemic for blastomycosis and was likely the exposure location for the three cases. All 3 patients recovered from illness.

Blastomyces identification is routinely performed by MDH only at the genus level. Therefore, the Centers for Disease Control and Prevention (CDC) determined the species in 4 isolates from the 2 blastomycosis clusters and performed Illumina (https://www.illumina.com) short-read sequencing (National Center

*Data for 2 isolates per cluster that underwent whole-genome sequencing and single-nucleotide polymorphism analyses.
†Likely exposure location on the basis of interviews with family members.
for Biotechnology Information BioProject accession no. PRJNA786864). To investigate genetic diversity between strains, we performed whole-genome single-nucleotide polymorphism (SNP) analysis using the MycoSNP version 0.19 analytical workflow (https://github.com/CDCgov/mycosnp). We used publicly available sequences from *B. dermatitidis* isolates (NCBI run nos. SRR11849827, SRR11849828, SRR11849829) as a reference. Neighbor-joining tree shows the genetic relationships between cluster A and B, which each comprised isolates from 2 patients, the *B. gilchristii* reference strain, and *B. dermatitidis* isolates. Numbers represent the SNPs for each strain. Ref., reference.

Both *B. dermatitidis* and *B. gilchristii* have been reported in Minnesota (2). We used whole-genome sequencing and SNP analysis to evaluate clusters of blastomycosis infections caused by *B. gilchristii* in Minnesota. The genomic data showed that cases within cluster A or B were closely related genetically, whereas clusters A and B were genetically distinct. *B. gilchristii* is likely responsible for a higher proportion of blastomycosis clusters than is currently known. Therefore, pairing genomic data with clinical information and geographic location can be used to monitor blastomycosis infections and determine whether they are clusters, outbreaks, or sporadic occurrences. Our findings demonstrate the utility of genomic analyses for investigating blastomycosis outbreaks, determining genetic diversity of *B. dermatitidis* and *B. gilchristii*, and identifying common sources of environmental exposures among cases.

Acknowledgments
We thank the Office of Advanced Molecular Detection, National Center for Emerging and Zoonotic Infectious Diseases, CDC, for supporting fungal disease molecular epidemiology; the MDH graduate students who conducted patient interviews; Mitsuru Toda for reviewing and providing feedback, and Suzanne Gibbons-Burgener for providing feedback.

MDH fungal disease epidemiology is supported by the Epidemiology and Laboratory Capacity for Infectious Diseases cooperative agreement with CDC.
**Tropheryma whipplei** Intestinal Colonization in Migrant Children, Greece

DOI: http://doi.org/10.3201/eid2809.220068

We obtained fecal samples from migrant children ≤12 years of age throughout hotspots in Greece and tested them for *Tropheryma whipplei* by using a quantitative PCR assay. We identified 6 genotypes of *T. whipplei*, 4 of which are newly described. Our findings suggest a high prevalence of *T. whipplei* in these regions.

*Tropheryma whipplei* is an intracellular bacterium recognized as the causative agent of enteric infection Whipple disease (1). *T. whipplei* intestinal colonization prevalence in humans depends on geographic area, age, and method of exposure (2). In Europe, *T. whipplei* has been detected in stool specimens in 2%–11% of healthy persons (1). The prevalence of *T. whipplei* intestinal colonization has been reported to be higher in children than in adults, suggesting an age-dependent presence (3). In developing countries, the rates are especially high, probably because of poor sanitary conditions (3). The prevalence of *T. whipplei* was shown to be high among children in Senegal (West Africa), reaching 75%; in contrast, the prevalence rate for children in France was 15% (1,4). *T. whipplei* has been associated with diarrhea in young children, suggesting a causative link between the bacterium and that symptom (5).

Because migrants often live without resources that enable appropriate personal hygiene, and because they have limited access to healthcare, they are exposed to many communicable infections. As a result, migrant populations have a poorer standard of overall physical health compared with the general population, and they suffer from a disproportionate burden of communicable diseases, including those caused by parasites, enteroviruses, and *Mycobacterium tuberculosis* (6). In Greece, in collaboration with the Hellenic National Public Health Organization, we routinely test stool samples of persons classified as migrants, with the intent of determining the...
