(Dated: May 1, 2014)

We solve the ab initio no-core shell model (NCSM) in the complete $8\Omega$ ($N_{\text{max}} = 8$) basis for $A = 7$ and $A = 8$ nuclei with two-nucleon and three-nucleon interactions derived within chiral effective field theory (EFT). We find that including the chiral EFT three-nucleon interaction in the Hamiltonian improves overall agreement with experimental binding energies, excitation spectra, transitions and electromagnetic moments. We predict states that exhibit sensitivity to including the chiral EFT three-nucleon interaction but are not yet experimentally.

I. INTRODUCTION

One of the most challenging problems in nuclear physics is to calculate nuclear properties starting from the strong interactions that accurately describe the nucleon-nucleon, three-nucleon and, possibly, four-nucleon systems. There are two major issues to overcome. First, the basic interactions among nucleons are complicated, they are not uniquely defined and there is ample evidence that more than just two-nucleon forces are important. Second, as a consequence of the complex nature of the inter-nucleon interactions, the quantum many-body problem for these strongly-interacting self-bound nuclei is very difficult to solve with good precision.

Interactions among nucleons are governed by QCD. In the low-energy regime under nuclear structure, QCD is non-perturbative and hard to solve directly to obtain these inter-nucleon interactions. New theoretical developments, however, allow us to connect QCD with low-energy nuclear physics through the promising bridge of chiral effective field theory ($\chi$EFT) [1]. The $\chi$EFT that includes pions but omits explicit nucleon excitations, predicts, along with the nucleon-nucleon (NN) interaction at the leading order, a three-nucleon (NNN) interaction starting at the 3rd order (next-to-next-to-leading order or N$^3$LO) [2,3], and even a four-nucleon (NNNN) interaction starting at the 4th order (N$^4$LO) [3]. The details of QCD dynamics are contained in parameters, low-energy constants (LECs), not fixed by the symmetry. These parameters can be constrained by experiment. A crucial feature of $\chi$EFT is the consistency between the $NN$, $NNN$ and $NNNN$ parts. As a consequence, at N$^3$LO and N$^4$LO, except for two LECs, assigned to two $NNN$ diagrams, the potential is fully constrained by the parameters defining the $NN$ interaction.

We have previously performed extensive calculations for light nuclei with the $\chi$EFT NN and $NNN$ interactions within the ab initio no-core shell model (NCSM) [3]. In particular, we investigated $A = 6$ and 7 nuclei [3], $A = 6, 10, 11, 12$ and 13 nuclei [7], and $A = 14$ nuclei [8]. The major conclusion obtained from these calculations was the confirmation of the significance of the $NNN$ interaction not only for the binding energies but also for the description of excitation energies and other observables such as magnetic dipole (M1) and Gamow-Teller (GT) transitions. The $NNN$ effects were found to be enhanced for the mid-$p$-shell nuclei [2], where, for example, the $^{10}$B ground-state spin is in agreement with experiment only when the $NNN$ interaction is included in the Hamiltonian. One of the dramatic consequences of including $\chi$EFT $NNN$ interactions has recently been found essential to explain the anomalous long lifetime (suppressed GT matrix element) of $^{13}$C [8]. We previously discovered another dramatic consequence of $NNN$ interactions in producing a strong enhancement of the B(M1) transition from the ground state of $^{12}$C to the $(J^\pi, T) = (1^+, 1)$ excited state [9], a transition that plays a major role in inelastic neutrino scattering. This early demonstration of the B(M1) enhancement featured the use of two realistic $NN$ interactions, Argonne V8’ [10] and CD-Bonn 2000 [11] each combined with the Tucson-Melbourne ”prime” $NNN$ interaction [12]. This B(M1) enhancement has been confirmed with $\chi$EFT $NN$ and $NNN$ interactions [7].

These calculations were performed by employing the Okubo-Lee-Suzuki (OLS) effective interaction approach [13] primarily in the 6$\hbar\Omega$ ($N_{\text{max}} = 6$) basis space. The exceptions are the $A = 6$ and $A = 14$ results which were obtained in the 8$\hbar\Omega$ space. It is desirable to extend all the calculations to larger basis sizes for several reasons. First, one would like to check the convergence of the smaller-space calculations. Second, the soft similarity-renormalization-group (SRG) evolved interactions are now available including the $NNN$ terms [13,16]. Variational calculations with these interactions require bases bigger than just 6$\hbar\Omega$ to...
fully establish the systematic trends. Also, the trends in results from different renormalization schemes, such as OLS and SRG, need to be compared with each other to better understand their advantages and drawbacks. Third, the importance-truncation approach has been successfully implemented for the NCSM calculations\cite{17,18}. That approach requires benchmarking against exact calculations in the same $N_{\text{max}}\hbar\Omega$ basis space. Fourth, the NCSM has been extended by the resonating group method (NCSM/RGM) for the description of nuclear reactions\cite{17}. The NCSM/RGM approach relies on the SRG interactions and requires basis expansion beyond $6\hbar\Omega$.

We report here our recent technical advances that allow us to perform the full-space $8\hbar\Omega$ calculations for all the $p$-shell nuclei. These technical advances include both the developments of the configuration interaction code MFDn\cite{20} and the development of the codes that calculate the $NNN$ matrix elements. In this paper, we present results for $A = 7, 8$ nuclei using the OLS method. Calculations for other $p$-shell nuclei using both the OLS and the SRG methods are underway and will be reported separately.

In Sect. \textbf{II} we briefly describe the NCSM approach and the technical advances that allowed us to extend the basis size of the calculations. Results for $A = 7$ and $A = 8$ nuclei are given in Sect. \textbf{III}. Conclusions are drawn in Sect. \textbf{IV}.

\textbf{II. AB INITIO NO-CORE SHELL MODEL}

In the \textit{ab initio} NCSM, we consider a system of $A$ point-like non-relativistic nucleons that interact by realistic $NN$ or $NN + NNN$ interactions. Unlike in standard shell model calculations, in the NCSM there is no inert core, all the nucleons are considered active - therefore the “no-core” in the name of the approach. Besides the employment of realistic $NN$ or $NN + NNN$ interactions, two other major features characterize the NCSM: i) the use of an harmonic oscillator (HO) basis truncated by a chosen maximal HO excitation energy $N_{\text{max}}\hbar\Omega$ (equivalently, the number of HO quanta $N_{\text{max}}$) above the unperturbed ground state (i.e. the lowest possible HO configuration) of the $A$-nucleon system; and ii) the use of effective interactions. The reason behind the choice of the HO basis is the fact that this is the only basis known (aside from the plane wave basis) that allows one to use single-nucleon coordinates and consequently the second-quantization representation without violating the translational invariance of the system. The powerful techniques based on second quantization and developed for standard shell model calculations can then be utilized - therefore the “shell model” in the name of the approach. As a downside, one has to face the consequences of the incorrect asymptotic behavior of the HO basis. The preservation of translational invariance is a consequence of the $N_{\text{max}}\hbar\Omega$ truncation.

In order obtain a reasonable approximation in a finite basis space (characterized by $N_{\text{max}}\hbar\Omega$) to the exact results in a complete (but infinite-dimensional) basis space, we construct an OLS effective interaction from the original realistic $NN$ or $NN + NNN$ potentials by means of a unitary transformation. We carry out this transformation at the two-body level (“NN only”) and at the level including both $NN$ and $NNN$ interactions (“NN + NNN”). In principle, one can perform the unitary transformation and generate many-body interactions up to and including all nucleons. However, going beyond $NN + NNN$ is technically very challenging. We may refer to our implementation of OLS as the cluster-truncated OLS approach.

The OLS effective interaction depends on the basis parameters ($N_{\text{max}}\hbar\Omega$) and recovers the original realistic $NN$ or $NN + NNN$ interaction as $N_{\text{max}}$ approaches infinity. In principle, one can also perform calculations with the unmodified, “bare”, original interactions. Such calculations are then variational with respect to $N_{\text{max}}$ and $\hbar\Omega$.

In this work, we use $NN$ and $NNN$ interactions derived within the chiral EFT. In particular, we employ the chiral $N^3\LO$ $NN$ interactions from Ref.\cite{21,22} and the chiral $N^2\LO$ $NNN$ interaction\cite{23} in the local form of Ref.\cite{24}. For the low-energy constants of the $NNN$ interaction not fixed by the two-nucleon data, we adopt values that reproduce the triton binding energy and half life\cite{25}. Next, we calculate three-body effective interaction from the chiral $NN + NNN$ interactions using the OLS procedure. As mentioned above, we adopt a cluster truncation which means that the three-body interaction is derived from full-space three-nucleon system solutions and the resulting three-body effective interaction is then input into the shell model code for the $A$-nucleon system. A large-scale diagonalization is then performed in the $A$-nucleon $N_{\text{max}}\hbar\Omega$ HO basis.

As the three-body effective interactions are derived in the Jacobi-coordinate HO basis but the $p$-shell nuclei calculations are performed using the shell model code in a Cartesian-coordinate single-particle Slater-determinant $M$-scheme basis, we need to perform a suitable transformation of the interactions. This transformation is a generalization of the well-known transformation on the two-body level that depends on HO Brody-Moshinsky brackets. Details of these transformations are given in Refs.\cite{6,26,27}. In this work, we use the particular version given in the appendix of Ref.\cite{6}. The corresponding computer code was improved compared to earlier applications\cite{7} that allow us now to perform the transformations up to $N_{\text{max}} = 8$ basis spaces for all $p$-shell nuclei. We note that for the $p$-shell nuclei with $A \geq 7$, the number of $NNN$ $M$-scheme matrix elements increases compared to the $A = 6$ case that was handled up to $N_{\text{max}} = 8$ already in Ref.\cite{7}. We note that the Jacobi-to-Slater-determinant $NNN$ transformation was further improved recently by utilizing a factorization with a $NNN$ coupled-JT scheme\cite{27} allowing to reach still larger $N_{\text{max}}$ spaces.
It is a challenge to utilize the M-scheme NNN interaction in a shell model code. First, one has to deal with a large number of the NNN matrix elements and, second, the number of the non-zero many-body Hamiltonian matrix elements increases by more than an order of magnitude compared to calculations with just NN interactions. Both these issues were successfully addressed in the newer versions of the shell model code MFDn, a hybrid OpenMP and MPI code [20]. The calculations discussed in this paper were performed on Franklin at NERSC using up to six thousand cores for the largest runs. Current versions of MFDn are capable of handling dimensions exceeding 1 billion with (2, 4, 6, 8) curves in Fig. 1 is very similar to those in Ref. [3] where different parameters for the chiral NNN interaction were employed for $^7$Li. There is a shift with the present interaction of about 1 MeV at $N_{max} = 6$ towards greater binding and towards better agreement with experiment when compared with the results of Ref. [3] with the chiral NNN interaction closest (called "3NF-A" in Ref. [3]) to the present case.

We show in Fig. 2 the dependence of the low-lying excited states of $^7$Li on the harmonic oscillator energy at the two highest values of basis space truncation, $N_{max} = 6$ and 8. Fig. 2 demonstrates the systematic trend to improved independence of $\hbar \Omega$ with increasing $N_{max}$ for the excitation spectra (slopes of the excitation energies decrease with increasing $N_{max}$). Furthermore, the shifts in the excitation energies when proceeding from $N_{max} = 6$ to 8 are less than the spread in the $\hbar \Omega$ dependence at $N_{max} = 6$ over the range of $\hbar \Omega$ depicted in Fig. 2.

Quantifying the uncertainties in our results for nuclear observables is a major challenge. The systematic uncertainties due to lack of complete convergence dominate our overall uncertainties by at least an order of magnitude. The actual uncertainties are dependent on the specific ob-

---

**FIG. 1:** (Color online) Calculated ground state energy of $^7$Li in the NCSM with chiral EFT $NN$ and $NNN$ interactions that reproduce the triton binding energy and half life. The dependence on the HO frequency and size of the basis is presented.

**FIG. 2:** (Color online) Calculated excitation energies of the lowest 5 excited states of $^7$Li in the NCSM with chiral EFT $NN$ and $NNN$ interactions that reproduce the triton binding energy and half life. The dependence on the HO frequency is presented at the two highest values of basis space truncation $N_{max} = 6$ (dashed lines) and 8 (solid lines). The experimental excitation energies are shown on the left for comparison.
servable as well as whether the observable is hindered or enhanced compared to phenomenological single-particle values. To give an example, we estimate the numerical uncertainties in our calculated gs energies and excitation energies to be around (50, 1) keV arising respectively from the numerical evaluation of (1) the effective NN or NN+NNN interactions for the selected basis space and (2) the numerical solution of the many-body eigenvalue problem. However, as we shall discuss now, our overall uncertainties are dominated by incomplete convergence with increasing basis size. Since we do not have converged calculations to calibrate these uncertainties, we will simply quantify specific measures of our basis space dependence. Convergence arises when these measures of basis space dependence vanish.

The results in Fig. 2 provide indications of our basis space dependence. For the present work, we adopt the following procedure to estimate the dependence of the excitation energies on the basis-space truncation. We quote two quantities: (1) one half of the total spread in the excitation energy over the range in ℏΩ shown in this figure at N_{max} = 8, and (2) the total shift in excitation energy obtained from the increment of N_{max} = 6 to 8 at the selected optimum frequency. These quantities are quoted in parenthesis beside each excitation energy result for the NN + NNN interaction in the tables below. For the excited states in the present work we present both estimates in the above respective order to show the state-by-state deviations in each quantity. For uniformity and completeness, we present two significant figures for each estimate.

Since many of the states we investigate are resonances and our basis lacks explicit coupling to the continuum, we expect, in accordance with the findings of Ref. [28], that broader resonances are associated with larger ℏΩ-dependence in the HO basis calculations. Thus, one may also interpret our first measure of basis-space dependence as a rough indicator of the resonance width. This may be useful for estimating relative widths [28].

From the N_{max} = 8 curve in Fig. 1 we select the optimal frequency as ℏΩ = 13 MeV for examining our results in greater detail. This adoption sets one of the inputs to the determination of the basis-space dependence in excitation energies as just described. We also define the basis-space dependence of our total gs energy as the difference in total energy at this adopted minimum for the basis space increment from N_{max} = 6 to 8. As an example, this produces the estimate of 0.44 MeV for the 7Li gs energy which is quoted in parenthesis next to the eigenvalue in Table I.

We observe a similarity in the N_{max} dependence or results in Figs. 1 and 2. In both cases, our estimated uncertainties range up to several hundred keV (see Table I). However, in the absence of a firm trend in N_{max} for our results, one should not take our quoted uncertainties as estimates of numerical accuracy but rather as characteristics of the dependence of the results on the presently available basis spaces.

We show the low-lying spectra of 7Li in Fig. 3 at the optimum frequency and at the sequence of N_{max} truncations corresponding to the curves in Fig. 1. The energies, radii and electromagnetic observables are summarized in Tables I and II, where we also include the 7Be results. We obtain the same level ordering for 7Be and 7Li which is also the same for both NN and the NN + NNN interactions with the exception of a reversal of the 7/2^- and 3/2^- levels in 7Be. That is, in 7Be, the experimental 7/2^- and 3/2^- levels are reversed compared to our results and the situation in 7Li. On the other hand, our NN + NNN ordering is in agreement with experiment for the 9 lowest states in 7Li.

Our calculated spectra for both of the A = 7 nuclei show a reasonable stability with respect to the frequency change. The results in Table I (and A = 8 results in Tables II and V below) indicate that there are residual differences between theoretical and experimental energies that are significantly larger than our quoted basis-space dependence of the calculated results. It will be interesting to see if the differences between theory and experiment persist once more accurate calculations become feasible. If they do, the question becomes whether these differences are significantly reduced, for example, when a chiral NNN interaction becomes available that is more complete than the one currently available [29].

We present in Table III a selection of results for magnetic moments, M1 transitions and other properties of the A = 7 nuclei. All electromagnetic observables are evaluated with the free-space electromagnetic coupling constants. That is, we do not employ effective charges or effective magnetic moments for the nucleons.

The results in Table III with NN alone and NN + NNN interactions are both in reasonable agreement with experiment. One observes that there is a trend for radii...
TABLE I: The $^7$Be and $^7$Li ground and excited state energies (in MeV) obtained using the chiral $NN$ and chiral $NN + NNN$ interactions. The HO frequency of $\hbar \Omega = 13$ MeV and the $8\hbar \Omega$ model space were used. Our measures of basis-space dependence are given for the last two significant figures of the quoted theory result. Two quantities, as explained in the dependence are given for the last two significant figures of text, are quoted in parenthesis for excitation energies with the $NN$ states of $^7$Li. Experimental values are from Ref. \[30\].

and quadrupole moments to increase with increasing basis size and/or decreasing frequency. This is, in part, a consequence of the incorrect asymptotics of the HO basis and also our basis space truncation. Convergence rates for the radii and quadrupole moment appear improved at a smaller HO frequency since they are less dependent on the basis truncation.

We have performed various tests to establish that our calculated electroweak observables, those near or greater than single-particle values, are accurate to three significant digits. However, we are not able to quantify the basis-space dependence for our electroweak observables at the present time. By presenting results at different values of $\hbar \Omega$ and $N_{\text{max}}$ we provide a preliminary indication of those dependences. Quantifying their systematic uncertainties more rigorously will require an extensive separate investigation. In the meantime, our best estimate of the exact theoretical result is the one obtained in the largest basis space with the optimum value of $\hbar \Omega$.

The magnetic moments and B(M1) values tend to be about 10% to 26% smaller in magnitude than experiment. We believe this is an acceptable range of difference since we have not included exchange current corrections which can easily be in the range needed to improve the agreement with experiment. Future work will address these corrections. In the meantime, we can offer support for this belief by citing the corrections due to two-body currents obtained in the ab initio evaluation of the the magnetic moment of the $^7$Li gs using GFMC techniques with AV18 plus Illinois-2 three-body forces \[31\].

In that investigation, the two-body currents raised the $^7$Li gs magnetic moment from 2.9 $\mu_N$ to 3.2 $\mu_N$. Similarly, the two-body currents changed the $^7$Be gs magnetic moment from -1.06 $\mu_N$ to -1.49 $\mu_N$. Both these corrections are in the direction and of the magnitude needed to explain the difference of our results from experiment.

We adopt the experimental gs rms charge radius for $^7$Li (2.44(4) fm) and $^6$Li (2.34(5) fm) from a recent detailed analysis of the experimental and theoretical gs properties of the Lithium isotopes \[32\].

We also adopt the corrections they define and evaluate (finite proton charge density, neutron charge density, etc.) in order to extract a point proton rms radius $r_p$ from the measured rms charge radius that we quote in our tables as the experimental value for $r_p$ to be compared with our theoretical results. Note that our theoretical $r_p$ is free of spurious cm motion effects.

We present our $^8$B and $^8$Li ground-state and excited-state energy results in Table III. The basis size dependence of the $^8$B spectra calculated using the chiral $NN + NNN$ interaction and the optimal HO frequency of $\hbar \Omega = 13$ MeV is shown in Fig. 4. Simiar conclusions can be drawn as for the $A = 7$ nuclei concerning convergence. The dependence of the gs energy on the basis size and the HO frequency is somewhat larger than was observed for the $A = 7$ nuclei. This may be due, in part, to greater proximity to breakup thresholds in the $A = 8$ nuclei we investigate here.

One noticeable difference between the chiral $NN$ and the chiral $NN + NNN$ predictions appears among the low-lying levels – an interchange of the order of the $0^+_1$ and $3^+_1$ states. We note that the $0^+_1$ state has not been observed experimentally. However, the recent Ref. \[33\] does claim observation of the low-lying $0^+_1$ resonance based on the R-matrix analysis of the $p-^7$Be scattering experiment performed in the energy range between 1.6 to 2.8 MeV in the center of mass. They suggest the $0^+_1$ resonance is at 1.9 MeV which places it below the experimental $3^+_1$ state. However, our calculated $0^+_1$ energy obtained with the chiral $NN$ and $NN + NNN$ interaction is above our calculated $3^+_1$ state. On the other hand, note that this $0^+_1$ state has a larger $\hbar \Omega$ dependence than lower-lying states which suggests a proper scattering treatment is needed for its
TABLE II: The $^7$Be and $^7$Li point-proton rms radii (in fm), ground-state quadrupole (in $\mu_N$), magnetic moments (in $\mu_N$) and M1 transitions (in $\mu_N$) obtained within the NCSM for different HO frequencies (given in MeV) and model spaces for the chiral $NN$ and chiral $NN + NNN$ interactions. Most experimental values are from Ref. [30]. The point proton rms radius $r_p$ for $^7$Be is evaluated from the experimental rms charge radius of 2.647(17) fm from Ref [32] using corrections of Ref [32] as discussed in the text. The point proton rms radius $r_p$ for $^7$Li is evaluated from the experimental rms charge radius of Ref [32] as discussed in the text.

TABLE III: The $^8$B and $^8$Li ground and excited state energies (in MeV) obtained using the chiral $NN$ and chiral $NN + NNN$ interactions. The HO frequency of $\hbar \Omega = 13$ MeV and the $8\Omega + \Omega$ model space were used. See the caption to table II and the text for explanation of the basis-space dependences quoted in parenthesis. Experimental values are from Ref. [33].

properties. It is known that the positions of resonances are affected by the coupling to the continuum as demonstrated, e.g. in Ref. [36] where the $^8$B and $^8$Li resonances were investigated within the NCSM/RGM approach.

In Table III, we also predict a significant number of additional levels in these $A = 8$ systems that are not yet known experimentally. The ordering of these predicted levels is sensitive to the presence of the NNN interaction so it would be very valuable to have additional experimental information on these states. We also note that many of these predicted states have larger basis-space dependences which are dominated by their HO frequency dependence in the $N_{max} = 8$ basis space. This suggests that these continuum states may be somewhat broader resonances than the established states since increasing frequency dependence in HO basis treatments of resonances has been correlated with increasing resonance width [28] as mentioned above.

In Table IV we compare $A = 8$ experimental and the-
sensitivity to ℏ IV.

sensitive to a presence of three-nucleon interaction in the 8 action the magnetic moment of results suggest that the A NN interaction alone predicts the opposite. Clearly, our NN interaction alone and the NN + NNN interaction, the results appear reasonably stable in going from Nmax = 6 to Nmax = 8. The role of the chiral EFT NNN interaction is to shift all calculated gs energies significantly closer to the experimental results. There appears to be a tendency to underbind these nuclei as one moves away from the minimum in the valley of stability.

Our calculated excitation levels of 8Be are compared to experiment in Table IV and Fig. 6. We note a good agreement of the level ordering compared to experiment and also a good stability of the spectrum with respect to the change of the model space size. An exception in this regard is the calculated first excited 0 state that is an intruder state with large multipoles as we did above for the 8Be-7Li case. A correlation exists between the B(M1; 1+ → 2+) transitions and the calculated magnetic moments also show sensitivity to ℏΩ since they change by 10% - 20% in the Ω values in Table IV.

Next, consider the B(M1; 1+ → 2+) transitions presented in Table IV. Here, the calculated matrix elements are 20% - 35% smaller than the experimental values. More significantly, the calculated results are nearly unchanged when the NNN interaction is included. Both these features are reminiscent of the B(M1; 1/2− → 3/2−) transitions in the A = 7 nuclei shown in Table III.

Our calculated gs energies of A = 8 nuclei are summarized in Table IV and shown in Fig. 6. With both the NN interaction alone and the NN + NNN interaction, the results appear reasonably stable in going from Nmax = 6 to Nmax = 8. The role of the chiral EFT NNN interaction is to shift all calculated gs energies significantly closer to the experimental results. There appears to be a tendency to underbind these nuclei as one moves away from the minimum in the valley of stability.

The theoretical results for a selection of electromagnetic observables as we did above for the A = 7 nuclei. Here, the radii and quadrupole moments are somewhat larger and closer to experiment in our chiral NNC calculations due, in part, to weaker binding. In addition, contrary to the 7Be-7Li case, we observe here an interesting difference between the NN and NN + NNN cases for the magnetic moment prediction. By including the NNN interaction the magnetic moment of 8Li is significantly greater than that of 7B in agreement with experiment, while the NN interaction alone predicts the opposite. Clearly, our results suggest that the A = 8 magnetic moments are sensitive to a presence of three-nucleon interaction in the Hamiltonian. These A = 8 magnetic moments also show sensitivity to ℏΩ since they change by 10% - 20% in the largest basis space over the range of ℏΩ values in Table IV.

More significantly, the calculated results are nearly unchanged when the NNN interaction is included. Both these features are reminiscent of the B(M1; 1/2− → 3/2−) transitions in the A = 7 nuclei shown in Table III.

Our calculated gs energies of A = 8 nuclei are summarized in Table IV and shown in Fig. 6. With both the NN interaction alone and the NN + NNN interaction, the results appear reasonably stable in going from Nmax = 6 to Nmax = 8. The role of the chiral EFT NNN interaction is to shift all calculated gs energies significantly closer to the experimental results. There appears to be a tendency to underbind these nuclei as one moves away from the minimum in the valley of stability.

Our calculated excitation levels of 8Be are compared to experiment in Table IV and Fig. 6. We note a good agreement of the level ordering compared to experiment and also a good stability of the spectrum with respect to the change of the model space size. An exception in this regard is the calculated first excited 0+0 state that is an intruder state with large multi-Ω components. The appearance of this state and the corresponding 2+ and 4+ excitations were discussed in detail in Ref. [33]. We also note that the existence of a 2+ intruder broad resonance was confirmed in the R-matrix analysis of the reactions...
energies are from Ref. [38]. The basis space dependencies, and the chiral NN energies, in MeV, of
NN interaction and found the gs energy to range from
-37.8 MeV to -42.0 MeV which spans our own result of
-38.60(44) MeV in Table I. The dependence on renormalization scale implies that higher-body effective interactions are required to obtain a stable result.

Extensive ab initio calculations of A=7 and A=8 nuclei have been performed with Variational Monte-Carlo and Green’s Function Monte Carlo methods using NN plus NNN interactions derived from meson-exchange theory. These works provide the most precise agreement between theory and experiment for the observables they investigate and are closer to convergence, in our view. In addition, they have evaluated meson-exchange current corrections to electroweak processes. Though our agreement with experiment is not as good and we do not yet incorporate exchange current corrections, we are able to expand the suite of observables to compare with experiment and to provide the platform for systematic improvements with anticipated future developments of the chiral interactions and exchange current corrections.
in the chiral approach.

More recently, a comprehensive review of the Unitary Correlation Operator Method (UCOM) [46] presents extensive results for light nuclei including $^7$Li using the Argonne V18 NN interaction [47]. With the UCOM method they obtain a variational upper bound on the $^{18}$NN interaction [47]. With the UCOM method though there are many differences in the calculations. Their spectra for $^7$Li through the first seven excited states are also in the experimental order but spread more than experiment as are our own spectra.

Among other efforts with $ab$ initio no-core methods to address some of the same nuclei investigated here with, we mention our efforts with an NN interaction derived by inverse scattering methods, JISP16 [48] applied to $^7$Li and $^8$Li [49] using the no-core full configuration (NCFC) method [50]. Results of those investigations also appear to be in rough accord with the results presented here. For example, the gs energy of $^7$Li and $^8$Li are -38.253(1) MeV and -39.485(16) MeV respectively, both within 500 keV of the results we report here.

IV. CONCLUSIONS

In this work, we used the Okubo-Lee-Suzuki renormalization of the chiral Hamiltonian specific to each model space employed and presented results for $A = 7$ and $A = 8$ nuclei. Our results demonstrate that the $NN$ interaction improves the agreement with experimental data not only for binding energies but also for excitation energies and other observables. Among other features, our results suggest that the $A = 8$ magnetic moments are especially sensitive to the presence of three-nucleon interaction in the Hamiltonian.

Taking into account our estimates of the basis-space dependence of our spectra given in Tables III and IV, we find that there are residual differences between theory and experiment that can now be attributed to the need for further improvements to our approach. Those improvements could originate from improved chiral 3-body interactions, adding chiral 4-body interactions and/or including effective 4-body interactions. We also recall that there is imperfect knowledge of the nonperturbative coupling constants in the currently-employed chiral NN + NNN interactions that could, if exploited, remove differences between the current theoretical results and experiment.

The present results will be useful for comparing with calculations performed with the SRG-evolved chiral interactions that are currently under way [51]. In this regard, the extension of the model space to the $8\hbar\Omega$ basis is significant as already proven in the case of $^6$Li calculations [10].

We have now extended the $ab$ initio no-core shell model calculations with two- and three-nucleon forces in the complete $8\hbar\Omega$ basis to all $p$-shell nuclei by technical advances of the shell model code MFDn and the codes that calculate and transform the three-body interaction matrix elements. As demonstrated in the $8\hbar\Omega$ results for the $A = 14$ nuclei [8] we have now the capability to calculate any $p$-shell nucleus in model spaces up to $8\hbar\Omega$ with matrix dimensions exceeding 1 billion with Hamiltonians that include $NNN$ interactions. This basis extension capability is also significant for a further refinement of the importance-truncation approach [18] and for the nuclear reaction applications within the NCSM/RGM method [19].

We also note that further improvements in the three-body interaction transformation algorithm and a new division of tasks between the shell-model and the three-body interaction transformation codes will allow one to reach even higher $N_{\text{max}}\hbar\Omega$ basis spaces. This is significant since both the importance truncation approach [18, 27] and the SU3-NCSM [52] provide access to much higher $N_{\text{max}}\hbar\Omega$ basis spaces with chiral EFT interactions.
