(Dated: August 14, 2020)

We analyze the weak-coupling instabilities that may arise when multiple high-order Van Hove points are present inside the Brillouin zone. The model we consider is inspired by twisted bilayer graphene, although the analysis should be more generally applicable. We employ a parquet renormalization group analysis to identify the leading weak-coupling instabilities, supplemented with a Ginzburg-Landau treatment to resolve any degeneracies. Hence we identify the leading instabilities that can occur from weak repulsion with the power-law divergent density of states. Four correlated phases are uncovered along distinct fixed trajectories, including the $s$-wave ferromagnetism, $p$-wave chiral/helical superconductivity, $f$-wave valley-polarized order, and $p$-wave polar valley-polarized order. The phase diagram is stable against band deformations which preserve high-order Van Hove singularity.

I. INTRODUCTION

2D multilayer moiré heterostructures constitute a major platform of modern condensed matter research. These systems manifest enlarged moiré superlattices and according nearly flat bands, thereby enjoy remarkably high experimental tunability with interlayer twist angle, vertical gating electric field, external magnetic field, and pressure. A main family of research on moiré heterostructures focuses on the twisted bilayer graphene, where the moiré flat bands can develop at small twist angles [1–6]. Unconventional superconductivity, insulating states, and other correlated phases have been observed experimentally, either at a ‘magic angle’ or under certain setup of the other conditions [7–20]. The properties of underlying band structures and the origins of correlated phases have attracted enormous interest.

For the correlated phases in twisted bilayer graphene, one popular scenario emphasizes the importance of the Van Hove singularity in the density of states [21–34]. Van Hove singularity can occur at the saddle points of the dispersion energy with divergent density of states [35]. These saddle points are generically present in the dispersive moiré flat bands of twisted bilayer graphene [7, 10, 13, 14, 16]. The model calculations show that the Van Hove singularity occurs near the half-fillings in both electron and hole branches [2–6]. Meanwhile, the corrections from Coulomb interaction may pin the Van Hove singularity to the Fermi surface at a broad range of doping [36, 37]. With the divergent density of states, the electronic correlations can receive significant amplification. Instabilities to the Fermi liquid may occur accordingly, with the energy scales remarkably enhanced compared to the conventional exponentially small ones.

By introducing the weakly repulsive interactions at Van Hove singularity, the investigations of potential correlated phases in twisted bilayer graphene have constituted an enormous literature [21–33]. These works address the interacting problems at the conventional Van Hove singularity, where logarithmically divergent density of states and Fermi surface nesting are relevant at weak coupling. The development of instabilities can be observed transparently in a renormalization group (RG) analysis [21–24]. With the Fermi surface nesting, the spin density waves can develop first at moderate RG scale, thereby trigger the true instabilities as the RG flow goes further [23, 38]. The leading instability usually occurs in the superconducting channels beyond $s$-wave. Meanwhile, the antiferromagnetic orders may become relevant at moderate coupling. However, recent experiments have uncov-

![FIG. 1. Tentative phase diagram of weakly repulsive electrons at the high-order Van Hove singularity in twisted bilayer graphene. Four potential correlated phases are uncovered, including the $s$-wave ferromagnetism ($s$FM), $p$-wave chiral/helical superconductivity ($pC/HSC$), $f$-wave valley-polarized order ($fVP$), and $p$-wave polar valley-polarized order ($pPVP$). The setup of interactions is the same as in Fig. 6 with additional perturbative intervalley exchange as in Fig. 7.](arXiv:2008.05485v1 [cond-mat.str-el] 12 Aug 2020)
ered correlated phases where the orders are more likely polarized [12, 15, 17] or nematic [10, 16, 20]. While the polarized orders may arise at moderate coupling as the conventional Stoner instability [22, 24] or through other mechanisms [39–43], a theory where these density orders can develop as robust weak-coupling instabilities remains to be uncovered.

A potential answer to such problem is indicated by the emergence of ‘high-order’ Van Hove singularity under particular setting, such as the magic angle [34]. In the moiré flat bands of twisted bilayer graphene, the number of saddle points can be different at different tunable parameters [2, 4]. The variation of saddle point number amounts to the splitting of each saddle point into a pair. At the critical point of splitting, the saddle point becomes high-order, with the density of states acquiring a much stronger power-law divergence. Such divergence can lead to significantly different phase diagram from the one at the conventional Van Hove singularity. The manifestations of high-order Van Hove singularity has been investigated in the context of cuprate materials [44, 45], doped intercalated graphene [46–48], strontium materials [49], bilayer graphene [50], and twisted bilayer transition metal dichalcogenide [51]. General discussions of the eligible band structures and locations of high-order Van Hove singularity have been conducted with complete classifications [52, 53]. For a single high-order Van Hove point, the renormalization group analysis uncovers an interacting fixed point [45]. This fixed point possesses divergent susceptibilities without developing long-range orders in various channels, thereby manifesting itself as a supermetal. When the high-order Van Hove singularity occurs at multiple points, the system may develop ferromagnetism as a leading weak-coupling instability of our interest [48, 50]. Superconductivity may also arise as a competing order. The indications from these works strongly suggest an analysis of high-order Van Hove singularity in twisted bilayer graphene, where polarized correlated phases may be uncovered.

In this work, we analyze the weakly repulsive electrons at the high-order Van Hove singularity in twisted bilayer graphene. Our study adopts the parquet RG analysis, which has been conducted at the conventional Van Hove singularity in square lattice [38, 54, 55], doped graphene [56], and twisted bilayer graphene [21–24], as well as at the high-order Van Hove singularity in doped intercalated graphene [48] and bilayer graphene [50]. Unlike [48, 50] we consider a setting (relevant for twisted bilayer graphene) when the high-order Van Hove points occur away from the Brillouin zone boundary, which qualitatively alters the analysis. We show that such a system is primarily dominated by the zero-momentum particle-hole and particle-particle susceptibilities, leading to the RG flows toward either spin and/or valley-polarized orders or superconductivity. Four fixed trajectories under RG are uncovered, where the leading instabilities are the $s$-wave ferromagnetism, $p$-wave superconductivity, as well as the $f$- and $p$-wave valley-polarized orders (Fig. 1).

We further examine the degeneracy breakdown in the multi-component irreducible pairing channels. The analysis shows that the chiral and helical orders are the energetically favored ground states in the $p$-wave superconductivity. Meanwhile, the polar order with spontaneous rotation symmetry breaking are favored in the $p$-wave valley-polarized order. The irrelevance of Fermi surface nesting suggest the stability of our results against band deformations preserving high-order Van Hove singularity. Such feature is significantly different from the conventional Van Hove singularity, where the results may be fragile against the reduction of Fermi surface nesting.

**II. HIGH-ORDER VAN HOVE SINGULARITY IN TWISTED BILAYER GRAPHENE**

The model we consider is inspired by twisted bilayer graphene. In the twisted bilayer graphene at small twist angle, the low-energy regime is dominated by two pairs of conduction and valence moiré flat bands [1–6]. These moiré flat bands are manifest in the small moiré Brillouin zone, which corresponds to the large moiré superlattice in real space. Each pair of flat bands originates from the interlayer hybridization of Dirac cones in one graphene valley. The effective low-energy theory is described by a two-orbital honeycomb lattice model at moiré lattice scale, where the orbitals $\tau = \pm$ label the moiré flat bands from the two graphene valleys. The dispersion energies in the two valleys $\varepsilon_{\pm,\mathbf{k}}$ are related under time-reversal symmetry $\varepsilon_{+,\mathbf{k}} = \varepsilon_{-,\mathbf{k}}$, and an intravally $C_{3z}$ rotation symmetry is also manifest. The system obeys a spin $SO(4) \sim SU(2)_+ \times SU(2)_-$ symmetry composed of the spin $SU(2)_\pm$ symmetries in the two valleys.

Van Hove singularity is generically present in the moiré flat bands of twisted bilayer graphene [7, 10, 13, 14, 16]. We focus on the special case where the singularity is ‘high-order’ [34], and is present at high-order saddle points in the moiré Brillouin zone (Fig. 2). Three points are present in each valley, sitting on the $\Gamma M$-lines and exhibit the dispersion energies

$$\varepsilon_{\mathbf{P},\mathbf{k}} = -\alpha k^2 + \gamma k_\parallel k_\perp^2 + \kappa k_\perp^4.$$  \hfill (1)

Here $k_\parallel$ and $k_\perp$ denote the momentum deviations from each high-order saddle point $\mathbf{P}$ parallel and perpendicular to the $\Gamma M$ line, respectively. The points in the two valleys are related by time-reversal symmetry $\varepsilon_{-\mathbf{P},-\mathbf{k}} = \varepsilon_{\mathbf{P},\mathbf{k}}$. The structure of high-order saddle point can be more easily seen in the representation $k_\perp = k_\parallel - (\gamma / 2\alpha) k_\perp^2$ and $k_\parallel = k_\perp$

$$\varepsilon_{\mathbf{P},\mathbf{k}} = A_+ k_\perp^4 - A_- k_\perp^2,$$  \hfill (2)

where $A_+ = \kappa + \gamma^2 / 4\alpha$ and $A_- = \alpha$. The dispersion energy is quadratic along one direction and quartic along the other one, with the sign changing for four times around the high-order saddle point $\mathbf{P}$. The Fermi surface is determined by two parabolic curves $k_\perp =$
proximating the Fermi surface with six patches in the energy. We thus construct the low-energy theory by approximating the Fermi surface with six patches in the vicinity of these points. Such patch model takes the form

\[ H = \sum_{\alpha \tau} (\varepsilon_{\alpha \tau} - \mu) \psi_{\alpha \tau}^\dagger \psi_{\alpha \tau} \]  

(4)

with the patch labels \( \alpha = 1, 2, 3 \) (Fig. 2). The size of each patch is defined by an ultraviolet (UV) energy cutoff \( \Lambda \). In the patch model, the set of relevant momenta includes those between various pairs of patches. We define \( Q^o \) as the momentum transfer between opposite patches, while \( Q^a, b \) lie between patches with different patch labels in the same and different valleys, respectively.

Assume that the interactions in the low-energy theory are weakly repulsive, short-ranged, and spin \( \text{SU}(2) \) symmetric. Projected on the patch model, the interactions can be classified into sixteen inequivalent types with different scattering processes among patches. These interactions can be labeled as \( g_{ij} \)

\[ H_{\text{int}} = \sum_{\alpha_1, \alpha_2} \sum_{\tau_1, \tau_2} g_{ij} \psi_{\alpha_1+\tau_1}^\dagger \psi_{\alpha_2+\tau_2} \psi_{\alpha_3+\tau_3} \psi_{\alpha_4+\tau_4} \]  

(5)

where \( i \) and \( j \) label the exchange, density-density, pair-hopping, and forward-scattering processes in the patch.

FIG. 2. High-order Van Hove singularity in twisted bilayer graphene and patch model. (a) Band structure with high-order Van Hove singularity in twisted bilayer graphene. The band structure is obtained from the tight-binding model in Ref. 4, with the nearest- \( t_1 \), second-nearest- \( t_2 \), and fifth-nearest- \( t_3 \) neighbor hoppings set as \( t_1 = 1, t_2 = 0.15, \) and \( t_3 = 0.2720717 \), respectively. Each figure illustrates the band structure from a valley \( \tau = \pm \). (b) The band structure (1) in the vicinity of a high-order saddle point \( P \) with \( \kappa = 0 \). (c) The setup of patch model, where the patches are set at the high-order saddle points.

\[ \{ (\gamma/2\alpha) \pm [\kappa/\alpha + \gamma^2/4\alpha^2]^{1/2} \} k_y^2 \] one of which becomes a straight line when \( \kappa = 0 \). These curves touch with each other tangentially at the high-order saddle point \( P \).

The high-order saddle points \( P \)’s manifest the high-order Van Hove singularity, where power-law divergence occurs in the density of states (Appendix A) \[ D(\varepsilon) \approx D_0 \left( \frac{\theta(\varepsilon) + 1}{\sqrt{2}} \theta(-\varepsilon) \right) |\varepsilon|^{-1/4}. \]  

(3)

Here the prefactor is \( D_0 = \Gamma(1/4)^2/(8\pi^{5/2}A_{1/2}^{-1/2}A_{1/4}^{1/4}) \), and we have set the Van Hove doping at zero chemical potential \( \mu = 0 \) for convenience. The power-law divergence is stronger than the logarithmic divergence at conventional Van Hove singularity. Moreover, an asymmetry between the two sides of Van Hove doping can be observed, which is absent at conventional Van Hove singularity. This feature originates from the different powers in the dispersion energies (2) above and below the Van Hove doping.

Due to the power-law divergence in the density of states, the high-order saddle points \( P \)’s are more dominant than the other parts of the Fermi surface at low energy. We thus construct the low-energy theory by approximating the Fermi surface with six patches in the vicinity of these points. Such patch model takes the form

\[ H = \sum_{\alpha \tau} (\varepsilon_{\alpha \tau} - \mu) \psi_{\alpha \tau}^\dagger \psi_{\alpha \tau} \]  

(4)

with the patch labels \( \alpha = 1, 2, 3 \) (Fig. 2). The size of each patch is defined by an ultraviolet (UV) energy cutoff \( \Lambda \). In the patch model, the set of relevant momenta includes those between various pairs of patches. We define \( Q^o \) as the momentum transfer between opposite patches, while \( Q^a, b \) lie between patches with different patch labels in the same and different valleys, respectively.

Assume that the interactions in the low-energy theory are weakly repulsive, short-ranged, and spin \( \text{SU}(2) \) symmetric. Projected on the patch model, the interactions can be classified into sixteen inequivalent types with different scattering processes among patches. These interactions can be labeled as \( g_{ij} \)

\[ H_{\text{int}} = \sum_{\alpha_1, \alpha_2} \sum_{\tau_1, \tau_2} g_{ij} \psi_{\alpha_1+\tau_1}^\dagger \psi_{\alpha_2+\tau_2} \psi_{\alpha_3+\tau_3} \psi_{\alpha_4+\tau_4} \]  

(5)

where \( i \) and \( j \) label the exchange, density-density, pair-hopping, and forward-scattering processes in the patch.

FIG. 3. Feynman diagrams. (a) Six primary interactions without intervalley exchange. The solid and dashed lines describe the electrons from patches with different patch labels, while single and double lines characterize the electrons from different valleys. (b) The three interactions with intervalley exchange. (c) The test vertices in the particle-hole and particle-particle channels at momenta \( 0 \) and \( Q^o \). (d) Susceptibilities captured by the test vertices.
and valley sectors, respectively. The order of spins is \( \sigma, \sigma', \sigma'' \), and \( \sigma \) in the interactions. Only nine interactions are eligible under momentum conservation. The interactions without intervalley exchange, including \( g_{14}, g_{22}, g_{24}, g_{32}, g_{42}, \) and \( g_{44} \), are the primary ones considered in our analysis [Fig. 3(a)]. Meanwhile, the interactions involving intervalley exchange, including \( g_{11}, g_{31}, \) and \( g_{41} \), are assumed weak as they exhibit large momentum transfer at atomic scale [Fig. 3(b)]. We will include these when necessary to lift degeneracies, but not otherwise.

The high-order Van Hove singularity can lead to the breakdown of perturbation theory in Fermi liquid. This is manifest in the divergence of various static susceptibilities in the particle-hole (ph) and particle-particle (pp) channels \( \Pi_{q}^{ph/pp} = \pm T \sum_{n} \int_{k} G_{\pm k+q} G_{\pm k}(\pm \omega_{n}) \). Here \( G_{\pm k}(\omega_{n}) \) is the free fermion propagator with fermionic Matsubara frequency \( \omega_{n} = (2n + 1)\pi T \). The Matsubara frequency summation leads to

\[
\Pi_{q}^{ph/pp} = - \int_{k} n_{F}(\pm k+q - \mu) - n_{F}(\pm k \pm \mu) \ ,
\]

where \( n_{F}(z) = (\exp(z/T) + 1)^{-1} \) is the Fermi function. We calculate the susceptibilities in the patch model and focus on the asymptotic limit \( \mu, T \ll \Lambda \). The singularity in the density of states dominates in this regime, thereby selects a set of relevant susceptibilities with leading power-law divergence.

Our analysis focuses on the Van Hove doping \( \mu = 0 \). At zero momentum \( q = 0 \), the particle-hole and particle-particle susceptibilities acquire the leading power-law divergence (Appendix A)

\[
\Pi_{0}^{ph} = \frac{1}{4} \Pi_{0}^{pp} \approx \Pi_{0} = D_{0} \frac{1 + 1/\sqrt{2}}{2} \frac{2 \cdot 1.6514}{2} T^{-1/4}.
\]

The origins of these divergences are attributed to the singular density of states and Cooper divergence. We further compute all of the susceptibilities with decreasing temperature \( T \rightarrow 0 \) numerically (Fig. 4). The results show that the leading power-law divergence also arises in both particle-hole and particle-particle channels at \( q = Q_{p}^{*} \). Such divergence is expected from the observation of Fermi surface nesting, which becomes maximal when the Fermi surface contains a straight line at \( \kappa = 0 \)

\[
\Pi_{Q_{p}^{*}}^{ph} \approx \frac{1}{2} \Pi_{0}^{pp}, \quad \Pi_{Q_{p}^{*}}^{pp} \approx 0.35 \Pi_{0}^{pp}.
\]

The rest of the susceptibilities are subleading and are irrelevant in the asymptotic limit.

We comment in passing on the situations when the doping is away from the high-order Van Hove singularity \( \mu \neq 0 \). Since the Cooper divergence does not depend on the chemical potential, the according infrared (IR) cutoff is always \( T \). However, the divergences from singular density of states and Fermi surface nesting generically manifest the cutoff \( \max\{\mu, T\} \). We thus expect \( \Pi_{0}^{pp} \) as the most divergent susceptibility away from the Van Hove doping.

### III. Renormalization Group

With the divergent susceptibilities at the high-order Van Hove singularity, according divergence can occur in the interactions at low-energy. Such breakdown of perturbation theory in Fermi liquid can be captured by a parquet renormalization group (RG) analysis [23, 38, 54–56]. The parquet RG analysis aims to identify the low-energy effective theory under renormalization. Starting from the UV cutoff \( \Lambda \) of the patch model, the shell of fast electron modes is progressively integrated out with decreasing temperature \( T \rightarrow 0 \). Such procedure leads to an evolving renormalized effective theory, where the interactions receive various one-loop corrections through the divergent susceptibilities. The evolution of the interactions form an RG flow toward a fixed point or a fixed trajectory. Making the standard 'fast-parquet' approximation, we admit only the susceptibilities with the leading power-law divergence \( \Pi_{0}^{pp} \). This approximation captures the RG flow in the asymptotic weak-coupling limit \( g \rightarrow 0 \).

The parquet RG procedure we employ is as follows. We assume the density of states diverges at a power \( -\epsilon \), which is treated as infinitesimal (but will ultimately be continued to \( \epsilon = 1/4 \)). At infinitesimal \( \epsilon \), short-range interaction is marginal, and we therefore compute a set of RG equations to one-loop order. Define the dimensionless RG time \( y = \ln(\Lambda/T) \), interactions \( \lambda_{ij} = \Pi_{0}^{pp} g_{ij} \), and relative susceptibilities \( \bar{a}_{q}^{ph/pp} = \Pi_{q}^{ph/pp}/\Pi_{0}^{pp} \). Focusing on the primary interactions without intervalley exchange, we derive the RG equations with the form \( \lambda_{ij} = \beta_{ij}(\{\lambda_{ij}\}) \)

![Fig. 4. Particle-hole and particle-particle susceptibilities at the high-order Van Hove singularity. Each curve indicates a rescaled static susceptibility \( \bar{\Pi}_{q}^{ph/pp} = \Pi_{q}^{ph/pp}/\Pi_{0} \).](image-url)
We find that all of the fixed points of the RG equations are determined by the condition that all of the eigenvalues are negative. A stable fixed point is thus determined by the eigenvectors. A negative eigenvalue indicates that the interactions read

\[ \delta \lambda = \frac{\lambda_{ij}}{y_c - y}. \]

Adopting the critical scaling in the RG equations leads to a set of algebraic equations for the critical interactions \( \lambda_{ij} \)'s. The potential fixed trajectories under RG can be identified with the solutions to these algebraic equations. Note that \( \lambda_{44} \) is finite for all of the nontrivial solutions. To examine the stability of the fixed trajectories, we analyze the RG flow of the reparametrized interactions \( x_{ij} = \lambda_{ij}/\lambda_{44} \) for \( i \neq 44 \) with an alternative RG time \( \lambda_{44} \) [23, 56, 57]

\[ \frac{dx_{ij}}{d\lambda_{44}} = \beta_{ij}^\tau \{x_{ij}\} = -x_{ij} + \frac{\epsilon x_{ij} + \beta_{ij} \{x_{ij}\}}{-\epsilon x_{44} + \beta_{ij} \{x_{ij}\}}. \]

Here the tree-level terms in the original RG equations are eliminated as they become irrelevant at divergent \( \lambda_{44} \). The fixed points \( \{x_{ij}\} = \{x_{ij}^*\} \) with \( \lambda_{44}(dx_{ij}/d\lambda_{44})_{\{x_{ij}\}} = 0 \) for these RG equations correspond to the fixed trajectories of the original RG equations (9). The stable fixed points are determined by having all of the eigenvalues of \( M^x \) negative, where

\[ M^x_{ij,k,l} = (\partial \beta_{ij}^x/\partial x_{kl})_{\{x_{mn}\}} = (\{x_{mn}\}). \]

We find five different stable fixed trajectories compatible with bare repulsion. To which fixed trajectory the system flows under RG depends on the setup of bare interactions.

### IV. Instability Analysis

The breakdown of perturbation theory at low-energy indicates that an instability to the Fermi liquid occurs. To probe the potential instabilities along the fixed trajectories, we introduce the test vertices in various particle-hole and particle-particle channels [Fig. 3(c)] [23, 58–60]

\[ \delta H = \sum [\Delta \psi^\dagger \psi^{(1)} + \text{H.c.}]. \]

The test vertices acquire corrections from the divergent susceptibilities under RG. Solving the flow equations of the test vertices (Appendix C), the irreducible pairing channels \( I \)'s are identified as the eigenmodes with

\[ \hat{\Delta}_I = -d_I \lambda_I \Delta_I. \]

| Channel | Pairings | Leading |
|---------|----------|---------|
| sPOM | \( \psi \dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d \psi \) | Yes |
| fVP | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d_1 \psi \) | Yes |
| dPOM | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) d_2 \psi \) | Yes |
| pVP | \( \psi^\dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) d_1 \psi \) | Yes |
| sFM | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) d \psi \) | Yes |
| fSP | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) d_1 \psi \) | Yes |
| pSP | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) d_2 \psi \) | Yes |
| CDW\( \omega \) | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) \psi \) | |
| SDW\( \omega \) | \( \psi^\dagger (\begin{pmatrix} \tau \end{pmatrix} \begin{pmatrix} \sigma \end{pmatrix}) \psi \) | |
| sSC | \( \psi^\dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d_0 [i(\tau^{\tau^\dagger})(\sigma^{\sigma^\dagger})(\psi^{(1)^T})] \) | |
| fSC | \( \psi^\dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d_0 [i(\tau^{\tau^\dagger})(\sigma^{\sigma^\dagger})(\psi^{(1)^T})] \) | |
| dSC | \( \psi^\dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d_1 [i(\tau^{\tau^\dagger})(\sigma^{\sigma^\dagger})(\psi^{(1)^T})] \) | |
| pSC | \( \psi^\dagger (\begin{pmatrix} \sigma \end{pmatrix} \begin{pmatrix} \tau \end{pmatrix}) d_2 [i(\tau^{\tau^\dagger})(\sigma^{\sigma^\dagger})(\psi^{(1)^T})] \) | |

### TABLE I. The irreducible pairing channels receiving leading-power-law divergence and the particle-hole and particle-particle pairings therein. Here \( \tau^\nu \) and \( \sigma^\nu \) with \( \nu = 0, 1, 2, 3 \) are the Pauli matrices in the valley and spin pairing representations, respectively. The last column indicates whether the leading instability can develop in each channel starting from weak repulsion. Note that the effect of intervalley exchange has been considered.
The interaction $\lambda_I$ in each channel is a linear combination of the interactions $\lambda_{ij}$’s in the patch model. Along the fixed trajectories, the test vertices undergo the critical scaling $\Delta_1 \sim (y_c - y)^{\beta_I}$ as the interactions (10) do. The exponent in each channel is determined by the critical interaction and the particle-hole/particle-particle susceptibility $\beta_I = d_I \lambda_I$.

Our analysis focuses on the irreducible pairing channels which can receive the leading power-law divergence. These include the particle-hole and particle-particle channels at momenta 0 and $Q^\circ$ (Table I)

$$
\begin{align*}
\lambda_{\text{POM}/fVP} &= -2\lambda_{14} + 4\lambda_{22} + 4\lambda_{24} + 2\lambda_{42} + \lambda_{44}, \\
\lambda_{dPOM/fVP} &= \lambda_{14} + 2\lambda_{22} - 2\lambda_{24} + 2\lambda_{42} + \lambda_{44}, \\
\lambda_{sFM/fSVP} &= -2\lambda_{14} - \lambda_{44}, \\
\lambda_{dFM/pSVP} &= \lambda_{14} - \lambda_{44}, \\
\lambda_{C/SDW} &= -\lambda_{42}, \\
\lambda_{s/FSC} &= 2\lambda_{32} + \lambda_{42}, \\
\lambda_{d/pSC} &= -\lambda_{32} + \lambda_{42}, \\
\lambda_{PDW} &= \lambda_{44}.
\end{align*}
$$

In the particle-hole branch, we have the zero-momentum $s$- and $d$-wave Pomeranchuk orders ($s/dPOM$), $f$- and $p$-wave valley-polarized orders ($f/pVP$), $s$- and $d$-wave ferromagnetism ($s/dFM$), and $f$- and $p$-wave spin-valley-polarized orders ($f/pSVP$). The even- and odd-parity channels carry the valley singlet and triplet pairings $\tau^{0,3}$, respectively. The momentum-space form factors manifest the three irreducible patch representations under $C_{3z}$ symmetry, including the nondegenerate $d_0 = (1/\sqrt{3})(1,1,1)$ and degenerate $d_1 = (1/\sqrt{6})(2,-1,-1)$, $d_2 = (1/\sqrt{2})(0,1,-1)$. There are also charge and spin density waves at $Q^\circ$ ($C/SDW^\circ$), where the valley triplet pairings $\tau^{1,2}$ are manifest and three degenerate orders can occur at the three momenta $Q^\circ$’s. On the other hand, the particle-particle branch contains the $s$-, $f$-, $d$-, and $p$-wave superconductivities ($s/f/d/pSC$) at zero momentum. The even- and odd-parity channels now correspond to the valley triplet and singlet pairings $\tau^{1,0}$, respectively, and the irreducible patch representations $d_a$’s are again manifest. At the three $Q^\circ$’s, the pair density waves ($PDW^\circ$) can develop with valley triplet pairings $\tau^{1,2}$.

To examine whether the instability occurs in an irreducible pairing channel, we probe the susceptibility with the test vertex in this channel [Fig. 3(d)]

$$
\chi_I(y) = T \frac{\delta^2 \ln Z(y)}{\delta \Delta_I(0) \delta \Delta_I(0)} \bigg|_{\Delta_I(0), \Delta_I(0), \psi^\dagger, \psi = 0}.
$$
Here $Z(y)$ denotes the partition function at scale $y$, which is obtained by integrating out the fast modes of electrons at $y' < y$. The susceptibility undergoes a flow under RG

$$
\chi_I = d_I \left| \frac{\Delta_I}{\Delta_I(0)} \right|^2
$$

and manifests a critical scaling $\chi_I \sim d_I (y_c - y)^{\alpha_I}$ along the fixed trajectories, as well. Here the exponent is determined by the test vertex exponent $\alpha_I = 2\beta_I + 1$. The susceptibility becomes divergent at $y = y_c$ as $\alpha_I < 0$, indicating the development of an instability. The leading instability occurs in the channel with the most divergent susceptibility, which manifests the most negative exponent $\alpha_I$ among all channels.

We identify the leading instabilities along the five stable fixed trajectories in our problem. These include the degenerate $s$-wave ferromagnetism/$f$-wave spin-valley-polarized order, degenerate $d/p$-wave superconductivities, $f$-wave valley-polarized order, $p$-wave valley-polarized order, and $s$-wave Pomeranchuk order.

We confirm that the first four instabilities are indeed accessible starting from bare repulsions (Fig. 5). The phase diagram is further obtained under various setup of bare interactions (Fig. 6). The interactions $\lambda_{14}$, $\lambda_{44}$ generically stabilize the degenerate $s$-wave ferromagnetism/$f$-wave spin-valley-polarized order. Meanwhile, increasing $\lambda_{22}$, $\lambda_{42}$ triggers the $f$-wave valley-polarized order. Finally, the $p$-wave valley-polarized order can occur in some regimes of the phase diagram. We do not see the $s$-wave Pomeranchuk order starting from bare repulsion, which may only be accessible when the bare attractions are involved. Importantly, the phase diagram is stable against the suppression of Fermi surface nesting by $\kappa \neq 0$ in the dispersion energy (1). This indicates that the key features are determined primarily by the zero-momentum particle-hole and particle-particle susceptibilities. With the stability against band deformations, our results may be robustly applicable across the twisted bilayer graphene systems under various conditions.

The phase diagram can be contrasted with the one of an SU(4) symmetric model without valley splitting [48]. In such model, the high-order saddle points sit at the centers of Brillouin zone boundaries. The correspondence between the instabilities in the two models can be identified. The instabilities with spin and/or valley polarization all correspond to the SU(4) flavor ferromagnetism. On the other hand, the even- and odd-parity pairings of superconductivities all correspond to the odd-exchange SU(4) flavor pairings. The zero-momentum irreducible pairing channels in the SU(4) symmetric model are classified primarily by the momentum-space form factors, which are either $s$- or $d$-wave. With the dominance of zero-momentum particle-hole and particle-particle susceptibilities in both models, a similarity between the phase diagrams is expected. However, the valley splitting generically leads to the distinctions between some correlated phases in twisted bilayer graphene, which are absent in the SU(4) symmetric model.

**V. WHAT INTERVALLEY EXCHANGE DOES**

To address the more realistic situations in the practical twisted bilayer graphene systems, we now include the repulsive intervalley exchange perturbatively $g_{14} \ll g_{22}, g_{44}$ [Fig. 3(b)] and examine their effects on the correlated phases. This introduces additional terms to the RG equations (9) as well as to the interactions in the irreducible pairing channels (14) (Appendices B and C). We find that the phase diagram without intervalley ex-

![Figure 6. Phase diagram of the potential instabilities. The color map indicates the critical scale $y_c = \ln(\Lambda/T_c)$, which is smaller in the phases and larger along the phase boundaries. In each two-interaction phase diagram, two of the interactions $\lambda_{ij} = \lambda_{ij}/\lambda_0$ are varied, and the rest ones are set at constant repulsion $\lambda_{ij} = \lambda_0 = 0.1$. The full set of two-interaction phase diagrams is demonstrated in Appendix D.](image-url)
VI. THE ORDERED STATES

Our RG analysis has uncovered four correlated phases that can develop at the high-order Van Hove singularity in twisted bilayer graphene. We now proceed to discuss the various interesting features that these phases can possess.

A. Ferromagnetism/valley-polarized order

For the s-wave ferromagnetism, the irreducible representation in the patch sector is $d_0$. The order parameter breaks the spin SU(2) symmetry spontaneously

$$\Delta = \left\langle \psi^\dagger \left( \frac{\sigma^0}{\sqrt{2}} \right) d_0 \psi \right\rangle,$$

which serves as a spontaneous Zeeman splitting

$$\Delta_k = \frac{1}{2} \Delta \cdot \sigma \tau^0$$

and separates the spin-up and down Fermi surfaces. The axial direction of spin lies along an arbitrary direction. Things are similar in the $f$-wave valley-polarized order, where the order parameter is

$$\Delta = \left\langle \psi^\dagger \left( \frac{\sigma^3}{\sqrt{2}} \right) d_0 \psi \right\rangle.$$

The only difference is that the valley polarization is now fixed instead of being arbitrary, and the gap function is

$$\Delta_k = \frac{1}{2} \Delta \tau^3 \sigma^0.$$

B. $p$-wave superconductivity

The $p$-wave superconductivity manifests a multicomponent order parameter

$$\Delta^a = \left\langle \psi^\dagger_a \left( \frac{\sigma}{\sqrt{2}} \right) d_a [i(\sigma^2)(\psi^\dagger_a)^T] \right\rangle$$

with $a = 1, 2$, which may support more interesting features than the nondegenerate channels. Note that the irreducible valley pairing representation has been reduced, and $\psi_\pm$ denote the electrons in the two valleys. The Ginzburg-Landau free energy is derived in the vicinity of mean-field critical temperature $T_c$ (Appendix E)

$$f = c^{(2)}(|\Delta_1|^2 + |\Delta_2|^2) + c^{(4)} \left\{ \left( |\Delta_1|^2 + |\Delta_2|^2 \right)^2 + |\Delta_1 \times \Delta_1|^2 + |\Delta_2 \times \Delta_2|^2 + \frac{1}{3} \left[ -2|\Delta_1|^2 |\Delta_2|^2 + \Delta_1^2 \Delta_2^2 + \bar{\Delta}_1^2 \Delta_2^2 - 2(\Delta_1 \times \Delta_2)^2 \right] \right\},$$

where the overbar denotes complex conjugate. In accordance with the development of superconductivity below...
time-reversal symmetry spontaneously and manifests the $\pm \Delta s$ order. The spin SU(2) symmetry is again broken spontaneously, and the gap function is

\[
\Delta_\pm = \Delta_\pm \mathbf{\hat{n}}_a,
\]

where the $\pm$ and $\pm$ refer to the chiral and helical superconductivities, respectively. The axially symmetric $\pm \Delta s$ order can be identified directly.

We see two ground states by inspecting the second line of the free energy. The first ground state is the $p \pm i \Delta$ chiral order (pCSC) at $\theta = 0, \pi$ and $\phi = \pm \pi/2$, where $\mathbf{\hat{n}}_1 = \pm \mathbf{\hat{n}}_2 = \mathbf{\hat{n}}$ and $\Delta_2 = \pm i \Delta_1$. This state breaks the time-reversal symmetry spontaneously and manifests the gap function

\[
\Delta_C^\pm (\mathbf{\hat{n}}) = \frac{1}{2} \Delta \tau^0 (d_1 \pm i d_2) (\mathbf{\hat{n}} \cdot \mathbf{\sigma}),
\]

whose phase winds for $\pm 2\pi$ around the Fermi surface

\[
\Delta_{C, \theta_k}^\pm (\mathbf{\hat{n}}) = \frac{1}{\sqrt{6}} \Delta e^{\pm i \theta_k} (\mathbf{\hat{n}} \cdot \mathbf{\sigma})
\]

with the polar angle $\theta_k$. The axial direction of the order parameter $\mathbf{\hat{n}}$ can lie in an arbitrary direction, corresponding to the spontaneous breakdown of spin SU(2) symmetry. On the other hand, the second ground state is the $p$-wave helical order (pHSC) at $\theta = \pi/2$ and $\phi = 0, \pi$, with $\mathbf{\hat{n}}_1 \cdot \mathbf{\hat{n}}_2 = 0$ and $\Delta_1 = \pm \Delta_2$. The time-reversal symmetry is preserved, and the gap function is

\[
\Delta_H^\pm (\mathbf{\hat{n}}_1, \mathbf{\hat{n}}_2) = \frac{1}{2} \Delta \tau^0 (d_1 \mathbf{\hat{n}}_1 + d_2 \mathbf{\hat{n}}_2) \cdot \mathbf{\sigma}
\]

with the momentum-space form

\[
\Delta_{\theta_k}^H (\mathbf{\hat{n}}_1, \mathbf{\hat{n}}_2) = \frac{1}{\sqrt{6}} \Delta (\cos \theta_k \mathbf{\hat{n}}_1 + \sin \theta_k \mathbf{\hat{n}}_2) \cdot \mathbf{\sigma}.
\]

This ground state can be regarded as a composition of two chiral orders, where the equal-spin pairings with opposite spins $\uparrow, \downarrow$ exhibit opposite phase windings $\pm 2\pi$. The spin SU(2) symmetry is again broken spontaneously, and a $\pm 2\pi$ winding in the plane formed by $\mathbf{\hat{n}}_1$ and $\mathbf{\hat{n}}_2$ can be observed around the Fermi surface.

The superconducting ground states exhibit fully gapped quasiparticle spectra and belong to distinct $Z$ topological classification [27, 61]. Since the two ground states sit at disjoint free energy minima in the order parameter space, a first-order phase transition is expected to occur in between.

C. $p$-wave valley-polarized order

The order parameter in the $p$-wave valley-polarized order is

\[
\Delta_a = \left\langle \psi^\dagger \left( \frac{\tau^3}{\sqrt{2}} \right) \left( \sigma^0 d_a \psi \right) \right\rangle
\]

with $a = 1, 2$. We derive the Ginzburg-Landau free energy in the vicinity of the critical temperature $T_c$ as for the $p$-wave superconductivity (Appendix E)

\[
\begin{align*}
&f = c^{(2)}(\Delta_1^2 + \Delta_2^2) + c^{(4)}(\Delta_1^2 + \Delta_2^2)^2 + c^{(6)}(\Delta_1^2 + \Delta_2^2)^3 \left( 1 + \frac{1}{10} \cos 6\theta \Delta \right) + c^{(8)}(\Delta_1^2 + \Delta_2^2)^4 \left( 1 + \frac{8}{35} \cos 6\theta \Delta \right) .
\end{align*}
\]

Here the angle $\theta = \tan^{-1}(\Delta_2/\Delta_1)$ is defined. The quadratic prefactor $c^{(2)} \sim T - T_c$ turns negative below $T_c$, where the valley-polarized order develops. At higher orders in the expansion, the prefactors $c^{(4)}$ and $c^{(8)}$ are positive, while $c^{(6)}$ is negative. The anisotropic terms exist and select particular directions under spontaneous $C_{1z}$ rotation symmetry breaking [62]. Since the octic order terms are perturbatively smaller than the sextic order ones, the free energy minima occur at $\theta = n\pi/3$ with $n = 0, 1, 2$. The gap function of such polar order (pVVP)

\[
\Delta_\phi = \frac{1}{2} \Delta \tau^3 (d_1 \cos \theta \Delta + d_2 \sin \theta \Delta)
\]

manifests one of the patch orders $(2, -1, -1), (-1, 2, -1)$, and $(1, -1, 2)$, and the momentum-space form reads

\[
\Delta_{\theta_k}(\theta \Delta) = \frac{1}{\sqrt{6}} \Delta \cos(\theta_k - \theta \Delta).
\]

Accordingly, the Fermi surface undergoes a deformation which is anisotropic in the momentum space.

VII. DISCUSSION

We have analyzed the correlated phases that may arise as weak-coupling instabilities when multiple high-order Van Hove points occur within the Brillouin zone, in a model inspired by twisted bilayer graphene. The parquet renormalization group analysis uncovers four different correlated phases starting from weak repulsion (Table II). These include the $s$-wave ferromagnetism, $p$-wave chiral/helical superconductivity, $f$-wave valley-polarized order, and $p$-wave polar valley-polarized order. The Fermi surfaces are present in the spin- and valley-polarized orders with splittings and/or anisotropic deformations, while the chiral and helical superconductivities are fully gapped. Significantly, the phase diagram is determined primarily by the zero-momentum particle-hole and particle-particle susceptibilities. This indicates the
| Phase | Broken symmetry | Low-energy spectrum | Experimental probe |
|-------|----------------|---------------------|--------------------|
| sFM   | $SU_c(2), T$   | Spin-splitted FS    | Magnetic susceptibility |
| pCSC  | $U_v(1), SU_s(2), T$ | Fully gapped | Quantized spin and thermal Hall effect |
| pHSC  | $U_v(1), SU_s(2)$ | Fully gapped | Quantized spin Hall effect |
| fV    | $U_v(1), T$   | Valley-splitted FS  | Valley Hall effect |
| pV    | $U_v(1), T, C_3$ | Anisotropic valley-splitted FS | Valley Hall effect, anisotropic LDOS or transport signal |

TABLE II. The potential correlated phases in our model and their features. Here $T$ is the time-reversal symmetry, while the symmetries with subscripts $c$, $s$, and $v$ are those in the charge, spin, and valley sectors, respectively. FS denotes the Fermi surface, and LDOS refers to the local density of states.

stability of our results against band deformations which preserve the high-order Van Hove singularity. Our work thus serves as a potential guide toward the understanding of experimentally observed correlated phases in twisted bilayer graphene under various conditions.

It is worth discussing the experimental manifestations of the correlated phases we uncover. The spin- and valley-polarized orders may be observed from the measurements of magnetic susceptibility and valley Hall effect, respectively. When spatial rotation symmetry is broken, the according anisotropy can be observed in the probe of local density of states [10, 16] or transport measurement [20]. The chiral and helical superconductivities can manifest topological responses. While the chiral ordered state has the quantized thermal and spin Hall effect, the helical ordered state exhibits the quantized spin Hall effect. Whether the characteristics of these correlated phases can be probed in the experimental twisted bilayer graphene systems deserves further examination.

Appendix A: High-order Van Hove singularity

We discuss the general properties of high-order Van Hove singularity in this section. Our discussion focuses on a high-order saddle point $P$ with the general form of dispersion energy in its vicinity

$$\varepsilon_{P,k} \approx A_+ k_+^{n_+} - A_- k_-^{n_-}. \quad (A1)$$

Here the prefactors $A_\pm > 0$ are assumed, $k = (k_+, k_-)$ denotes the momentum deviation from $P$, and $n_\pm$ are positive even integers.

1. Density of states

The density of states $D(\varepsilon) = \delta_{\varepsilon} F_{FS, k}$ acquires a power-law divergence at the high-order saddle point $P$. Here $F_{FS}$ represents the Fermi surface at the energy $\varepsilon$. Assume an ultraviolet (UV) cutoff $\Lambda$ for the dispersion energy and define the parameters $a_\pm = A_\pm^{1/n_\pm}$.

$$D(\varepsilon) = \int_0^\Lambda \prod_{s=\pm} \frac{2}{2\pi n_s A_s^{1/n_s}} da_s a_s^{1/n_s} - 1 \delta(a_+ - a_- - \varepsilon). \quad (A2)$$

Integrating out $a_+$ and setting $a = a_-$, the integral becomes

$$D(\varepsilon) = \prod_{s=\pm} \frac{1}{\pi n_s A_s^{1/n_s}} \times \int_0^\Lambda da (a + \varepsilon)^{1/n_s} a^{1/n_s} - 1 \theta(a + \varepsilon). \quad (A3)$$

We separate the integrals for $\varepsilon > 0$ and $\varepsilon < 0$. With the reparametrization $u = a/|\varepsilon|$ and the scaling dimension

$$\epsilon = 1 - \frac{1}{n_+} - \frac{1}{n_-}, \quad (A4)$$

the integral reads

$$D(\varepsilon) = \prod_{s=\pm} \frac{1}{\pi n_s A_s^{1/n_s}} |\varepsilon|^{-\epsilon} \left[ \theta(\varepsilon) \int_0^{\Lambda/|\varepsilon|} du \frac{u^{1/n_s - 1}}{(1 + u)^1/n_s + \varepsilon} + \theta(-\varepsilon) \int_{-1}^{\Lambda/|\varepsilon|} du \frac{(u - 1)^{1/n_s - 1}}{u^{1/n_s + \varepsilon}} \right]. \quad (A5)$$

Performing a further reparametrization $u' = u - 1$ for the second integral and pushing the limit of UV cutoff to infinity $\Lambda/|\varepsilon| \to \infty$, we rewrite the integral in terms of the Beta functions

$$D(\varepsilon) = \prod_{s=\pm} \frac{1}{\pi n_s A_s^{1/n_s}} |\varepsilon|^{-\epsilon} \left[ \theta(\varepsilon) B(1/n_+, \epsilon) + \theta(-\varepsilon) B(1/n_-, \epsilon) \right]. \quad (A6)$$

Using $B(x, y) = \Gamma(x)\Gamma(y)/\Gamma(x + y)$ and $\Gamma(1 - z)\Gamma(z) = \pi/\sin(\pi z)$, we arrive at the final form

$$D(\varepsilon) = D_0 \left[ \theta(\varepsilon) \sin \frac{\pi}{n_+} + \theta(-\varepsilon) \sin \frac{\pi}{n_-} \right] |\varepsilon|^{-\epsilon}. \quad (A7)$$
with the prefactor

\[ D_0 = \frac{\Gamma(\epsilon)}{\pi} \prod_{s=\pm} \frac{\Gamma(1/n_s)}{\pi n_s A_s^{1/n_s}}. \]  

(A8)

Note that an asymmetry can generically be present on the two sides of the Van Hove doping.

2. Susceptibility

We now proceed to calculate the static susceptibilities (6) in the particle-hole (ph) and the particle-particle (pp) channels at the high-order Van Hove singularity. We focus particularly on the zero-momentum susceptibilities, while the finite-momentum ones depend generically on the structure of Fermi surface. The zero-momentum particle-hole susceptibility \( \Pi_0^{ph} = \Pi_{q=0}^{ph} \) corresponds directly to the power-law divergent density of states (A7)

\[ \Pi_0^{ph} = -\int d\epsilon D(\epsilon) \partial_\epsilon n_F(\epsilon - \mu) = \frac{D_0}{2} T^{-\epsilon} \int dx|x|^{-\epsilon} \cosh^{-2} \frac{x - \mu/T}{2} \times \frac{1}{2} \left[ \theta(x) \sin \frac{\pi}{n_+} + \theta(-x) \sin \frac{\pi}{n_-} \right]. \]  

(A9)

At \( \mu = 0 \), we have

\[ \Pi_0^{ph} = \frac{D_0}{2} T^{-\epsilon} \int dx|x|^{-\epsilon} \cosh^{-2} \frac{x}{2} \times \frac{1}{2} \left[ \theta(x) \sin \frac{\pi}{n_+} + \theta(-x) \sin \frac{\pi}{n_-} \right]. \]  

(A10)

Note that the power-law divergence is now controlled by the natural infrared (IR) cutoff \( T \) with the same exponent \( -\epsilon \). Meanwhile, the zero-momentum particle-particle susceptibility enjoys the Cooper divergence

\[ \Pi_0^{pp} = -\int d\epsilon D(\epsilon) \frac{n_F(\epsilon - \mu) - n_F(\epsilon + \mu)}{2(\epsilon - \mu)}. \]  

(A11)

A direct evaluation leads to

\[ \Pi_0^{pp} = \frac{D_0}{2} T^{-\epsilon} \int dx|x|^{-\epsilon} \frac{\tanh[(x - \mu/T)/2]}{x - \mu/T} \times \left[ \theta(x) \sin \frac{\pi}{n_+} + \theta(-x) \sin \frac{\pi}{n_-} \right], \]  

which becomes

\[ \Pi_0^{pp} = \frac{D_0}{2} \frac{T^{-\epsilon} \int dx|x|^{-\epsilon} \tanh(x/2)}{x} \times \left[ \theta(x) \sin \frac{\pi}{n_+} + \theta(-x) \sin \frac{\pi}{n_-} \right]. \]  

(A12)

which becomes

\[ \Pi_0^{pp} = \frac{D_0}{2} \frac{T^{-\epsilon} \int dx|x|^{-\epsilon} \tanh(x/2)}{x} \times \left[ \theta(x) \sin \frac{\pi}{n_+} + \theta(-x) \sin \frac{\pi}{n_-} \right]. \]  

(A13)

at \( \mu = 0 \). Pushing the UV cutoff to infinity for the integral, an approximate relation with \( \Pi_0^{ph} \) [45] can be established by an integration by parts

\[ \Pi_0^{pp} = \frac{1}{\epsilon} \Pi_0^{ph}. \]  

(A14)

Appendix B: Renormalization group equations

In this section, we derive the renormalization group (RG) equations for the nine eligible interactions in the patch model. Consider the one-loop corrections to the interactions with decreasing temperature \( T \to 0 \) (Fig. 8). The according RG equations for the primary interactions without intervalley exchange read (Figs. 9 and 10)

\[ \dot{\lambda}_{14} = c\lambda_{14} + d_{0}^{ph}\lambda_{14}(\lambda_{14} + 2\lambda_{44}) + \left\{ d_{0}^{ph}\lambda_{11}(\lambda_{11} + 2\lambda_{41}) \right\}_{wIVE}, \]

\[ \dot{\lambda}_{22} = c\lambda_{22} + d_{0}^{ph}[2\lambda_{22}(\lambda_{14} - 2\lambda_{24} - \lambda_{44}) + 2\lambda_{42}(\lambda_{14} - 2\lambda_{24})] + \left\{ 2d_{0}^{ph}(\lambda_{11}\lambda_{24} + \lambda_{11}\lambda_{44} + \lambda_{42}\lambda_{41}) \right\}_{wIVE}, \]

\[ \dot{\lambda}_{24} = c\lambda_{24} + d_{0}^{ph}[2\lambda_{22}(\lambda_{14} - 2\lambda_{24} - \lambda_{44}) + 2\lambda_{42}(\lambda_{14} - 2\lambda_{24} - \lambda_{44}) + 2\lambda_{44}(\lambda_{14} + \lambda_{44})] + \left\{ 2d_{0}^{ph}(\lambda_{11}\lambda_{24} + \lambda_{11}\lambda_{44} + \lambda_{42}\lambda_{41}) \right\}_{wIVE}, \]

\[ \dot{\lambda}_{32} = c\lambda_{32} - \lambda_{32}(\lambda_{32} + 2\lambda_{42}) + \left\{ -\lambda_{31}(\lambda_{31} + 2\lambda_{41}) \right\}_{wIVE}, \]

\[ \dot{\lambda}_{42} = c\lambda_{42} + d_{0}^{ph}[4\lambda_{22}(\lambda_{14} - 2\lambda_{24}) - 4\lambda_{42}\lambda_{44}] + \left\{ d_{0}^{ph}\lambda_{42}^2 - (2\lambda_{32}^2 + \lambda_{42}^2) \right\}_{wIVE}, \]

\[ \dot{\lambda}_{44} = c\lambda_{44} + d_{0}^{ph}[2\lambda_{14}(\lambda_{14} + 2\lambda_{24}) - 4\lambda_{22}^2 - 4\lambda_{44}^2 - 2\lambda_{42}^2 + \lambda_{42}^2] - d_{0}^{pp}\lambda_{44}^2 + \left\{ 4d_{0}^{ph}[2\lambda_{11}(\lambda_{11} + 2\lambda_{22}) + \lambda_{41}(\lambda_{41} + 2\lambda_{42})] \right\}_{wIVE}. \]  

B1

The curly brackets indicate the corrections with intervalley exchange (wIVE), and are not included in the analysis with only primary interactions (Sec. III). Meanwhile, the corrections to the interactions with intervalley exchange

FIG. 8. One-loop corrections to the interactions.
FIG. 9. RG equations of the primary interactions without intervalley exchange (Part one). The red diagrams are those involve
the intervalley exchange.

take the form (Fig. 11)
\[
\begin{align*}
\dot{\lambda}_{11} &= \epsilon \lambda_{11} + 2d_{\text{ph}}(\lambda_{11}\lambda_{14} + \lambda_{11}\lambda_{44} + \lambda_{14}\lambda_{41}), \\
\dot{\lambda}_{31} &= \epsilon \lambda_{31} - 2(\lambda_{31}\lambda_{32} + \lambda_{31}\lambda_{42} + \lambda_{32}\lambda_{41}), \\
\dot{\lambda}_{41} &= \epsilon \lambda_{41} + 2d_{\text{ph}}(2\lambda_{11}\lambda_{14} + \lambda_{41}\lambda_{44}) \\
&\quad + 2d_{Q\text{ph}}\lambda_{41}(-\lambda_{41} + \lambda_{42}) - 2(2\lambda_{31}\lambda_{32} + \lambda_{41}\lambda_{42}).
\end{align*}
\]

The whole set of RG equations (B1) and (B2) is included in the analysis with intervalley exchange (Sec. V).

Appendix C: Test vertex analysis

We conduct the test vertex analysis in the irreducible pairing channels which can receive the leading power-law divergence. These include the pairing channels at momenta \(0\) and \(Q_o\) in both particle-hole and particle-particle branches. Introducing the perturbing Hamiltonian \(\delta H\) with infinitesimal test vertices, we identify the one-loop corrections to the test vertices under RG (Fig. 12). Such procedure is captured by a set of differential equations. The diagonalization to such equations indicates the irreducible pairing channels and the interactions therein.

1. Particle-hole channels

a. Zero-momentum equal-spin pairings

We first consider the test vertices involving zero-momentum particle-hole pairings with equal spin. The perturbing Hamiltonian \(\delta H\) reads

\[
\delta H = \sum_{\alpha\tau\sigma} \Delta_{\alpha\tau\sigma} \psi_{\alpha\tau\sigma}^\dagger \psi_{\alpha\tau\sigma}
\]
with real test vertices $\Delta_{\alpha\sigma}$. The test vertices receive the corrections from the zero-momentum particle-hole susceptibility $\Pi_{\text{ph}}^0$ under RG [Fig. 12(a)]. This procedure is captured by the equation

$$\dot{\Delta}_{\alpha\sigma} = -d_{\text{ph}}^0 \left[ -\lambda_{14} \Delta_{\alpha\sigma} - \lambda_{11} \sum_{\beta \neq \alpha} \Delta_{\beta\tau\sigma} + \left\{ \sum_{\tau \neq \tau'} \left( -\lambda_{41} \Delta_{\alpha\tau'\sigma} - \lambda_{11} \sum_{\beta \neq \alpha} \Delta_{\beta\tau'\sigma} \right) \right\}_{\text{wIVE}} + \sum_{\sigma'} \left( \lambda_{44} \Delta_{\alpha\tau\sigma'} + \lambda_{24} \sum_{\beta \neq \alpha} \Delta_{\beta\tau\sigma'} \right) + \sum_{\tau \neq \tau'} \left[ \lambda_{42} \Delta_{\alpha\tau'\sigma'} + \lambda_{22} \sum_{\beta \neq \alpha} \Delta_{\beta\tau'\sigma'} \right] \right].$$

(C2)

The diagonalization in the patch sector identifies two pairing channels $l = 0, 1$ with different patch orders $d_0$ and $d_{1,2}$, respectively

$$\dot{\Delta}_{l\tau\sigma} = -d_{\text{ph}}^0 \left[ \lambda^1_l \Delta_{l\tau\sigma} + \left\{ \lambda^4_l \sum_{\tau \neq \tau'} \Delta_{l\tau'\sigma} \right\}_{\text{wIVE}} + \sum_{\sigma'} \right] \left( \lambda^2_{l} \Delta_{l\tau\sigma'} + \lambda^3_{l} \sum_{\tau \neq \tau'} \Delta_{l\tau'\sigma'} \right).$$

(C3)

Here the interactions are defined as

$$\lambda^0_1 = -2\lambda_{14} - \lambda_{44}, \quad \lambda^1_1 = \lambda_{14} - \lambda_{44},$$

$$\lambda^2_0 = 2\lambda_{24} + \lambda_{44}, \quad \lambda^1_2 = -\lambda_{24} + \lambda_{44},$$

$$\lambda^3_0 = 2\lambda_{22} + \lambda_{42}, \quad \lambda^3_1 = -\lambda_{22} + \lambda_{42},$$

$$\lambda^4_0 = -2\lambda_{11} - \lambda_{41}, \quad \lambda^4_1 = \lambda_{11} - \lambda_{41} \text{ wIVE.}$$

(C4)

We next diagonalize the equation in the spin sector, leading to two pairing channels $s = 0, 1$ with spin singlet and
triplet pairings, respectively.
\[ \tilde{\Delta}_{trs} = -d_0^{ph} \left( \lambda_{l_2}^t \Delta_{trs} + \lambda_{l_1}^t \sum_{\tau \neq \tau'} \Delta_{tr's} \right). \]  
(C5)

The interactions in the equation now read
\[ \lambda_{l_1}^t = 2 \lambda_1^t + \lambda_2^t, \quad \lambda_{l_1}^t = \lambda_1^t, \]
\[ \lambda_{l_0}^t = 2 \lambda_1^t + \left\{ \lambda_1^t \right\}_{\text{wIVE}}, \quad \lambda_{l_1}^t = \left\{ \lambda_1^t \right\}_{\text{wIVE}}. \]
(C6)

Finally, we diagonalize the equation in the valley sector and get two pairing channels \( v = e, o \) with even and odd valley pairings, respectively. The equation takes the form (13)
\[ \tilde{\Delta}_{lus} = -d_0^{ph} \lambda_{lxe} \Delta_{lus} \]  
(C7)

with the interactions
\[ \lambda_{lxe} = \pm \lambda_2^t + \lambda_1^t. \]  
(C8)

There are eight irreducible pairing channels in total. The first ones are the \( s- \) and \( d- \) wave Pomeranchuk orders \( (s/dPOM) \), as well as the \( f- \) and \( p- \) wave valley-polarized orders \( (f/pVP) \). The interactions \( \lambda_{sPOM/fVP} = \lambda_{0e/o0} \) and \( \lambda_{dPOM/pVP} = \lambda_{1e/o0} \) are derived as
\[ \lambda_{sPOM/fVP} = -2 \lambda_1^t - 4 \lambda_{22} + 4 \lambda_{24} \pm 2 \lambda_{42} + \lambda_{44} \]
\[ + \left\{ \mp 2 \lambda_{11} \mp \lambda_{41} \right\}_{\text{wIVE}}, \]
\[ \lambda_{dPOM/pVP} = \lambda_{14} \mp 2 \lambda_{22} - 2 \lambda_{24} \pm 2 \lambda_{42} + \lambda_{44} \]
\[ + \left\{ \pm \lambda_{11} \mp \lambda_{41} \right\}_{\text{wIVE}}. \]  
(C9)

Meanwhile, there are \( s- \) and \( d- \) wave ferromagnetisms \( (s/dFM) \), as well as the \( f- \) and \( p- \) wave spin-valley-polarized orders \( (f/pSVP) \). The interactions \( \lambda_{sFM/fSVP} = \lambda_{0e/o1} \) and \( \lambda_{dFM/pSVP} = \lambda_{1e/o1} \) take the form
\[ \lambda_{sFM/fSVP} = -2 \lambda_{14} - \lambda_{44} + \left\{ \mp 2 \lambda_{11} \mp \lambda_{41} \right\}_{\text{wIVE}}, \]
\[ \lambda_{dFM/pSVP} = \lambda_{14} - \lambda_{44} + \left\{ \pm \lambda_{11} \mp \lambda_{41} \right\}_{\text{wIVE}}. \]  
(C10)

b. Zero-momentum opposite-spin pairings

We next consider the zero-momentum particle-hole pairings with opposite spins. The perturbing Hamiltonian reads
\[ \delta H = \sum_{\alpha \tau, \sigma > \sigma'} \left( \Delta_{\alpha \tau \sigma} \psi_{\alpha \tau \sigma}^{\dagger} \psi_{\alpha \tau \sigma'} + \text{H.c.} \right), \]  
(C11)

where the test vertices \( \Delta_{\alpha \tau \sigma} \) receive corrections from the zero-momentum particle-hole susceptibilities \( \Pi_{0}^{\text{ph}} \) under RG [Fig. 12(b)]. The according equation reads
\[ \Delta_{\alpha \tau \sigma} = -d_0^{ph} \left[ -\lambda_{44} \Delta_{\alpha \tau \sigma'} - \lambda_{14} \sum_{\beta \neq \alpha} \Delta_{\beta \tau \sigma'} \right. \]
\[ + \left\{ \sum_{\tau \neq \tau'} \left( -\lambda_{41} \Delta_{\alpha \tau' \sigma} - \lambda_{11} \sum_{\beta \neq \alpha} \Delta_{\beta \tau' \sigma'} \right) \right\}_{\text{wIVE}}. \]  
(C12)

The diagonalization in the patch sector identifies two pairing channels \( l = 0, 1 \) with different patch orders \( d_0 \).
A further diagonalization in the valley sector finds two pairing channels $v = e, o$ with even and odd valley pairings, respectively

$$\Delta_{lv\sigma\sigma'} = -d_{0}^{ph}\lambda_{lv}\Delta_{lv\sigma\sigma'}. \quad \text{(C15)}$$

The interactions in these two channels are

$$\lambda_{le/o} = \lambda_{1} + \left\{ \pm \lambda_{2}^{2} \right\}_{\text{wIVE}}. \quad \text{(C16)}$$

The four irreducible pairing channels correspond to the $s$- and $d$-wave ferromagnetisms (FM), as well as the $f$- and $p$-wave spin-valley-polarized orders. Note that the interactions $\lambda_{\text{FM/FVP}} = \lambda_{le/o}$ and $\lambda_{\text{FM/pSVP}} = \lambda_{le/o}$ are consistent with (C10) from the equal-spin pairings.

### 2. Particle-particle channels

#### a. Superconducting channels

For the zero-momentum particle-particle pairing channels, the perturbing Hamiltonian (12) induced by the test vertices is

$$\delta H = \sum_{\alpha, \tau < \tau', \sigma\sigma'} (\Delta_{\alpha\tau\sigma\sigma'}\psi_{\alpha\tau\sigma}^{\dagger}\psi_{\alpha'\tau'\sigma}^{\dagger} + \text{H.c.}) \quad \text{(C20)}$$

The test vertices receive the corrections from the zero-momentum particle-particle susceptibilities $\Pi_{0}^{pp}$ under RG [Fig. 12(d)], as captured by the equation

$$\Delta_{\alpha\tau\sigma\sigma'} = -d_{Q}^{ph}(-\lambda_{2})\Delta_{\alpha\tau\sigma\sigma'}. \quad \text{(C18)}$$

We immediately conclude that the interactions in the according charge and spin density wave channels (C/SDW) are

$$\lambda_{C/SDW} = -\lambda_{2}. \quad \text{(C19)}$$
The diagonalization in the patch sector identifies two pairing channels $l = 0, 1$ with different patch orders $d_0$ and $d_{1,2}$, respectively

$$\Delta_{l\sigma\sigma'} = -\left(\lambda_1^l \Delta_{l\sigma\sigma'} + \left\{ \lambda_2^l \sum_{\tau' \neq \tau \sigma \sigma'} \Delta_{l\tau'\sigma\sigma'} \right\}_{\text{aIV}} \right).$$

The interactions here are derived as

$$\lambda_0^l = 2\lambda_{32} + \lambda_{42}, \quad \lambda_1^l = -\lambda_{32} + \lambda_{42},$$

$$\lambda_3^l = 2\lambda_{31} + \lambda_{41}, \quad \lambda_2^l = -\lambda_{31} + \lambda_{41}.$$  \hspace{1cm} (C23)

A further diagonalization in the valley sector uncovers two pairing channels $v = e, o$ with even and odd valley pairings, respectively

$$\Delta_{lve\sigma\sigma'} = -\lambda_{lv} \Delta_{lve\sigma\sigma'},$$

and the interactions are

$$\lambda_{le/o} = \lambda_1^l + \left\{ \pm \lambda_2^l \right\}_{\text{wIV}}.$$ \hspace{1cm} (C24)

We thus identify the four superconducting channels with $s_+$, $f_-$, $d_0$, and $p$-wave orders ($s/f/d/pSC$). The interactions $\lambda_{s/fSC} = \lambda_{le/o}$ and $\lambda_{d/pSC} = \lambda_{le/o}$ are derived as

$$\lambda_{s/fSC} = 2\lambda_{32} + \lambda_{42} + \left\{ \pm 2\lambda_{31} \pm \lambda_{41} \right\}_{\text{wIV}},$$

$$\lambda_{d/pSC} = -\lambda_{32} + \lambda_{42} + \left\{ \mp \lambda_{31} \pm \lambda_{41} \right\}_{\text{wIV}}.$$ \hspace{1cm} (C26)

**b. Pair density waves**

With the test vertices coupled to the particle-particle pairings at finite momenta $Q^n$’s, the perturbing Hamiltonian

$$\delta H = \sum_{\alpha \tau \sigma \sigma'} (\Delta_{\alpha \tau \sigma \sigma'} \psi^\dagger_{\alpha \tau \sigma} \psi^\dagger_{\alpha \tau \sigma} + \text{H.c.})$$ \hspace{1cm} (C27)

is introduced. The test vertices receive the corrections from the finite-momentum particle-particle susceptibilities $\Pi_{Q^n}^{PP}$ under RG [Fig. 12(e)], and is described by the equation

$$\Delta_{\alpha \tau \sigma \sigma'} = -d_{PP}^{\alpha \tau \sigma} \lambda_{44} \Delta_{\alpha \tau \sigma \sigma'},$$ \hspace{1cm} (C28)

The interaction in the according pair density wave channels is thus identified as

$$\lambda_{PDW} = \lambda_{44}.$$ \hspace{1cm} (C29)

**Appendix D: Phase diagram**

In Sec. IV, we have shown selected two-interaction phase diagrams of the potential instabilities from weak repulsion (Fig. 6). Here we list the full set of two-interaction phase diagrams (Fig. 13), from which the features discussed in Sec. IV may be more easily observed.

**Appendix E: Ginzburg-Landau free energy**

Our RG analysis has uncovered two potential instabilities with multi-component structures. These include the $p$-wave superconductivity and the $p$-wave valley-polarized order. The degeneracy breakdown in these multi-component channels can be solved by the Ginzburg-Landau analysis. By expanding the free energy with respect to the infinitesimal order parameters near the critical temperature, the energetically favored ground states are determined through the free energy minimization. Here we derive the expanded free energy near the critical temperature, known as the Ginzburg-Landau free energy. The results are then adopted in the analysis in Sec. VI, where the energetically favored ground states are identified.

1. **$p$-wave superconductivity**

We project the interacting model onto the $p$-wave superconducting channel. The action reads

$$S = \int_{\tau} \left[ \sum_{\kappa} \psi_{\kappa}^\dagger \left( \partial_\tau + \xi_\kappa \right) \psi_{\kappa} + g_{pSC} \left( \mathbf{P}_1^\dagger \cdot \mathbf{P}_1 + \mathbf{P}_2^\dagger \cdot \mathbf{P}_2 \right) \right],$$ \hspace{1cm} (E1)

where $\tau$ is the imaginary time and the pairing operator

$$\mathbf{P}_a = \psi^\dagger_+ \left( \frac{\sigma}{\sqrt{2}} \right) d_a [i(i\sigma^2)(\psi^\dagger_T)]$$ \hspace{1cm} (E2)

is defined. We have reduced the irreducible valley pairing representations and take $\psi_\pm$ as in the $\kappa = \pm$ valleys, respectively. The interaction is taken negative $g_{pSC} < 0$. Conduct a Hubbard-Stratonovich transformation, where the pairing operators are decoupled by the bosonic complex vector order parameters $\mathbf{D}_{1,2}$. Impose the static condition for the order parameters $\mathbf{D}_a(\tau) = \mathbf{D}_a$. Defining the Nambu spinor $\Psi = (\psi_+, i[\sigma^2](\psi^\dagger_T))^T$ and integrating it out in the Matsubara frequency representation $\Psi = \sqrt{T} \sum_n \Psi_n e^{-i\omega_n \tau}$, we arrive at the mean-field free energy

$$f = \frac{1}{g_{pSC}} \left( |\mathbf{D}_1|^2 + |\mathbf{D}_2|^2 \right) - \text{Tr} \ln(-G^{-1}).$$ \hspace{1cm} (E3)

The inverse Gor’kov Green’s function has been defined

$$G^{-1} = \left( \sum_a \mathbf{D}_a \cdot \frac{G_{\pm}^{-1} \mathbf{D}_a \cdot [\sigma/\sqrt{2}] d_a}{G_{\pm}^{-1}} \right),$$ \hspace{1cm} (E4)

where the free electron and hole propagators are $G_{\pm} = [i\omega_n + (\varepsilon_\pm - \mu)]^{-1}$.

We expand the free energy with respect to the infinitesimal order parameters near the critical temperature $T_c$. Define $G_0(\mathbf{D}_{1,2} = 0)$ and $\Delta = G^{-1} - G_0^{-1}$. Ignoring the constant part of the free energy, we perform the
expansion up to quartic order

\[
f = \frac{1}{|g_{pSC}|}(|\Delta_1|^2 + |\Delta_2|^2) + \frac{1}{2} \text{Tr}(G \hat{\Delta})^2 + \frac{1}{4} \text{Tr}(G \hat{\Delta})^4. \tag{E5}
\]

Here the infinitesimal expansion parameter reads

\[
(G \hat{\Delta})^2 = \frac{1}{2}G_+G_- \sum_{ab} d_a d_b \\
\times \text{diag}([\Delta_a \cdot \sigma][\Delta_b \cdot \sigma], [\Delta_a \cdot \sigma][\Delta_b \cdot \sigma]). \tag{E6}
\]

The quadratic order terms in the free energy are

\[
f^{(2)} = \frac{1}{|g_{pSC}|}(|\Delta_1|^2 + |\Delta_2|^2) + \frac{1}{4} \text{Tr} \left[ G_+G_- \sum_{ab} d_a d_b \\
\times \text{diag}([\Delta_a \cdot \sigma][\Delta_b \cdot \sigma], [\Delta_a \cdot \sigma][\Delta_b \cdot \sigma]) \right]. \tag{E7}
\]
Utilizing $\text{Tr}(\sigma^i \sigma^j) = 2\delta_{ij}$ and $\text{Tr}(d_ad_b) = \delta_{ab}$, we obtain

$$f^{(2)} = \left[ \frac{1}{|g_{\text{sc}}|} + 2\text{Tr}(G_+ G_-) \right] (|\Delta_1|^2 + |\Delta_2|^2)$$

(E8)

with the square bracket term taking the form $T - T_c$ and turning negative below $T_c$. Meanwhile, the quartic order terms read

$$f^{(4)} = \frac{1}{16} \text{Tr} \left[ G_+^2 G_-^2 \sum_{abcd} d_ad_bd_c d_d \right.$$ \hspace{1cm} \begin{align*}
& \times \text{diag}([\Delta_a \cdot \sigma][\Delta_b \cdot \sigma][\Delta_c \cdot \sigma][\Delta_d \cdot \sigma], \]
& \quad [\Delta_a \cdot \sigma][\Delta_b \cdot \sigma][\Delta_c \cdot \sigma][\Delta_d \cdot \sigma]) \Big{]} 
\end{align*}

$$+ \frac{1}{3} \sum_{a \neq b} \left[ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)ight]
$$

$$+ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)
$$

$$+ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)) \Big{]} \right.$$ \hspace{1cm} \begin{align*}
&= \frac{1}{16} \text{Tr}(G_+^2 G_-^2)
\end{align*}

(E9)

where the term $\text{Tr}(G_+^2 G_-^2)$ can be verified positive. The nonvanishing traces in the patch sector are $\text{Tr}(d_1^2) = \text{Tr}(d_2^2) = 1/2$ and $\text{Tr}(d_1^2 d_2^2) = \text{Tr}(d_1 d_2 d_1 d_2) = 1/6$. This implies

$$f^{(4)} = \frac{1}{16} \text{Tr}(G_+^2 G_-^2)
$$

\hspace{1cm} \begin{align*}
& \times \left\{ \sum_a \text{Tr}(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)
\right. 
\end{align*}

$$+ \frac{1}{3} \sum_{a \neq b} \left[ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)
$$

$$+ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)
$$

$$+ \text{Tr}(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)) \Big{]} \right. 
$$

(E10)

In the spin sector, the nonvanishing terms are $\text{Tr}(\sigma^i)^4 = 2$ and $\text{Tr}((\sigma^i)^2(\sigma^j)^2) = -\text{Tr}(\sigma^i \sigma^j \sigma^j \sigma^i) = 2$ for $i \neq j$, leading to

$$\text{Tr}[(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)]
$$

$$= 2 \sum_i \Delta_{a_i} \Delta_{b_i} \Delta_{c_i} \Delta_{d_i} + 2 \sum_{i \neq j} \Delta_{a_i} \Delta_{c_j} \Delta_{b_j} \Delta_{d_i}
$$

$$- \Delta_{a_i} \Delta_{b_j} \Delta_{c_i} \Delta_{d_j} + \Delta_{a_i} \Delta_{b_i} \Delta_{c_j} \Delta_{d_i}) \right.$$ \hspace{1cm} \begin{align*}
&= 2 \sum_i |\Delta_a|^4 + 2 |\Delta_a||\Delta_a^\dagger|^2,
\end{align*}

$$\text{Tr}[(\Delta_a \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)]
$$

$$= 2 |\Delta_a|^2 |\Delta_b|^2 - 2 |\Delta_a||\Delta_b|^2 + 2 |\Delta_a||\Delta_b|^2,
$$

$$\text{Tr}[(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)]
$$

$$= 2 |\Delta_a|^2 |\Delta_b|^2 - 2 |\Delta_a||\Delta_b|^2 + 2 |\Delta_a||\Delta_b|^2,
$$

$$\text{Tr}[(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)(\Delta_a \cdot \sigma)(\Delta_b \cdot \sigma)]
$$

$$= 4 |\Delta_a||\Delta_b|^2 - 2 |\Delta_a||\Delta_b|^2 - 2 |\Delta_a||\Delta_b|^2.
$$

The quartic terms are then identified as

$$f^{(4)} = \frac{1}{8} \text{Tr}(G_+^2 G_-^2) \left\{ (|\Delta_1|^2 + |\Delta_2|^2)^2 
$$

$$+ |\Delta_1 \times \Delta_1|^2 + |\Delta_2 \times \Delta_2|^2
$$

$$+ \frac{1}{3} [-2 |\Delta_1|^2 |\Delta_2|^2 - \Delta_1^2 \Delta_2^2 - \Delta_1^2 \Delta_2^2]
$$

$$+ 2 (|\Delta_1 \cdot \Delta_2|^2 + 2 (|\Delta_1 \cdot \Delta_2|^2
$$

$$- 4 |\Delta_1 \cdot \Delta_2|^2 + 4 |\Delta_1 \cdot \Delta_2|^2) \right\}.
$$

(E13)

With the identities

$$|\Delta_1 \times \Delta_2|^2 = |\Delta_1|^2 |\Delta_2|^2 - |\Delta_1 \cdot \Delta_2|^2,
$$

$$|\Delta_1 \times \Delta_2|^2 = |\Delta_1|^2 |\Delta_2|^2 - |\Delta_1 \cdot \Delta_2|^2,
$$

$$|\Delta_1 \times \Delta_2|^2 = \Delta_1^2 \Delta_2^2 - (\Delta_1 \cdot \Delta_2)^2,
$$

the quartic terms can be reformulated as

$$f^{(4)} = \frac{1}{8} \text{Tr}(G_+^2 G_-^2) \left\{ (|\Delta_1|^2 + |\Delta_2|^2)^2 
$$

$$+ |\Delta_1 \times \Delta_1|^2 + |\Delta_2 \times \Delta_2|^2
$$

$$+ \frac{1}{3} [-2 |\Delta_1|^2 |\Delta_2|^2 + \Delta_1^2 \Delta_2^2 + \Delta_2^2 \Delta_1^2]
$$

$$- 2 (|\Delta_1 \times \Delta_2|^2 - 4 |\Delta_1 \times \Delta_2|^2)
$$

$$+ 4 |\Delta_1 \times \Delta_2|^2 - 4 |\Delta_1 \times \Delta_2|^2 \right\}.
$$

(E15)

Combining these results, we obtain the Ginzburg-Landau free energy (22) which is adopted in Sec. VI.

2. $p$-wave valley-polarized order

Projecting the interacting model onto the $p$-wave valley-polarized order channel, we have the action

$$S = \int \tau \left[ \psi^\dagger (\partial_\tau + \xi) \psi + \frac{g_{\text{VP}}}{2} \left( P_1^\dagger \cdot P_1 + P_2^\dagger \cdot P_2 \right) \right].$$

(E16)

Here the interaction is taken negative $g_{\text{VP}} < 0$ and the pairing operator

$$P_a^\dagger = \psi^\dagger \left( \frac{\tau_3}{\sqrt{3}} \right) \left( \frac{\sigma^0}{\sqrt{3}} \right) d_a \psi$$

is defined. We perform a Hubbard-Stratonovich transformation, where the pairing operators are decoupled by the bosonic real scalar order parameters $\Delta_{1,2}$. Impose the static condition for the order parameter $\Delta_a(\tau) = \Delta_a$.

Integrating the fermions out in the Matsubara frequency representation $\psi = \sqrt{T} \sum_n \psi_n e^{-i\omega_n \tau}$, we arrive at the mean-field free energy

$$f = \frac{2}{|g_{\text{VP}}|} (\Delta_1^2 + \Delta_2^2) - \text{Tr} \ln(-G^{-1}).$$

(E18)
The inverse Green’s function is defined

\[ G^{-1} = G^{-1} + \sum_a \Delta_a \left( \frac{\tau^3}{\sqrt{2}} \right) \left( \frac{\sigma^0}{\sqrt{2}} \right) d_a \]  

(E19)

with the free electron propagator \( G = [i\omega_n - (\varepsilon - \mu)]^{-1} \).

We expand the free energy with respect to the infinitesimal order parameters near the critical temperature. Define \( G_0 = G_0(\Delta_{1,2} = 0) \) and \( \Delta = G^{-1} - G_0^{-1} \). Ignoring the constant part of the free energy, we perform the expansion up to octic order

\[ f = \frac{2}{|g_{\text{VP}}|} (\Delta_1^2 + \Delta_2^2) + \frac{1}{2} \text{Tr}(G_0 \Delta)^2 + \frac{1}{4} \text{Tr}(G_0 \Delta)^4 + \frac{1}{6} \text{Tr}(G_0 \Delta)^6 + \frac{1}{8} \text{Tr}(G_0 \Delta)^8. \]  

(E20)

The expansion parameter reads

\[ G_0 \Delta = \frac{1}{2} G \sum_a d_a \Delta_a \tau^3 \sigma^0. \]  

(E21)

Note that the odd-power terms all vanish since \( \text{Tr}[(\tau^3)^n] = \text{Tr}(\tau^3) = 0 \) for odd \( n \)'s. The quadratic terms read

\[ f^{(2)} = \left[ \frac{2}{|g_{\text{VP}}|} + \frac{1}{2} \text{Tr}(G^2) \right] (\Delta_1^2 + \Delta_2^2). \]  

(E22)

with the square bracket term \( \sim T - T_c \) turning negative below \( T_c \), and the quartic terms are

\[ f^{(4)} = \frac{1}{32} \text{Tr}(G^4)(\Delta_1^2 + \Delta_2^2)^2 \]  

(E23)

with positive prefactor. For the sextic terms, we have

\[ f^{(6)} = \frac{1}{96} \text{Tr} \left[ G^6 \sum_{abdef} d_a d_b d_c d_d d_e d_f \Delta_a \Delta_b \Delta_c \Delta_d \Delta_e \Delta_f \right]. \]  

(E24)

The nonvanishing traces of \( d_a \)'s are \( \text{Tr}(d_1^6) = 11/36 \), \( \text{Tr}(d_2^6) = 1/36 \), \( \text{Tr}(d_1^2 d_2^4) = 1/12 \), and \( \text{Tr}(d_2^6) = 1/4 \), and the traces of their permutations. This implies

\[ f^{(6)} = \frac{1}{96} \text{Tr}(G^6)(\Delta_1^2 + \Delta_2^2)^3 \left[ \frac{10}{36} + \frac{1}{36} \cos 6\theta_\Delta \right]. \]  

(E25)

where \( \theta_\Delta = \tan^{-1}(\Delta_2/\Delta_1) \) and the prefactor is negative. At octic order

\[ f^{(8)} = \frac{1}{512} \text{Tr}(G^8) \sum_{abdefgh} \text{Tr}(d_a d_b d_c d_d d_e d_f d_g d_h) \times \Delta_a \Delta_b \Delta_c \Delta_d \Delta_e \Delta_f \Delta_g \Delta_h, \]  

(E26)

the nonvanishing traces of \( d_a \)'s are \( \text{Tr}(d_1^8) = 43/216 \), \( \text{Tr}(d_2^8) = 1/216 \), \( \text{Tr}(d_1^4 d_2^4) = 1/72 \), \( \text{Tr}(d_1^2 d_2^6) = 1/24 \), \( \text{Tr}(d_2^8) = 1/8 \), and the traces of their permutations. The octic order terms are then obtained as

\[ f^{(8)} = \frac{1}{512} \text{Tr}(G^8)(\Delta_1^2 + \Delta_2^2)^4 \left[ \frac{35}{216} + \frac{1}{27} \cos 6\theta_\Delta \right]. \]  

(E27)

with positive prefactor. Combining these results, we obtain the Ginzburg-Landau free energy (29) which is adopted in Sec. VI.
