SESSION 2018

AGREGATION
CONCOURS EXTERNE

Section : BIOCHIMIE - GÉNIE BIOLOGIQUE

ÉTUDE DE DOSSIER SCIENTIFIQUE ET TECHNOLOGIQUE

Durée : 4 heures

L'usage du dictionnaire anglais-français est autorisé.
L'usage de tout ouvrage de référence, de tout autre dictionnaire et de tout matériel électronique (y compris la calculatrice) est rigoureusement interdit.

Dans le cas où un(e) candidat(e) repère ce qui lui semble être une erreur d'énoncé, il (elle) le signale très lisiblement sur sa copie, propose la correction et poursuit l'épreuve en conséquence.
De même, si cela vous conduit à formuler une ou plusieurs hypothèses, il vous est demandé de la (ou les) mentionner explicitement.

NB : La copie que vous rendez ne devra, conformément au principe d'anonymat, comporter aucun signe distinctif, tel que nom, signature, origine, etc. Si le travail qui vous est demandé comporte notamment la rédaction d'un projet ou d'une note, vous devrez impérativement vous abstenir de signer ou de l'identifier.
L’édition du génome : le système CRISPR-Cas

L’édition du génome, notamment chez les eucaryotes, fait l’objet d’intenses recherches et les différentes techniques développées ouvrent un large champ d’applications.

A l’aide des articles proposés dans le dossier technique et en lien avec le contexte de l’étude, présenter le travail de recherche, tant dans sa dimension scientifique que dans ses aspects technologiques, et ses applications innovantes dans le domaine de la santé. Le candidat veillera également à proposer des mises en perspectives pédagogiques, prolongements des travaux présentés, en lien avec les connaissances générales exigées pour des étudiants de niveau BAC +2. Lors de la composition, l’analyse critique, la maîtrise scientifique et l’esprit de synthèse des candidats seront également appréciés.

Le dossier technique comporte deux parties :

Revue : A CRISPR CASe for high-throughput silencing
Jacob Heintze, Christin Luft and Robin Ketteler
Frontiers in Genetics, vol. 4, article 193, October 2013

Publication : CRISPR-Cpf1 correction of muscular dystrophy mutations in human cardiomyocytes and mice
Yu Zhang, Chengzu Long, Hui Li, John R. McAnally, Kedryn K. Baskin, John M. Shelton, Rhonda Bassel-Duby, Eric N. Olson
Science Advances, vol. 3, April 2017
INFORMATION AUX CANDIDATS

Vous trouverez ci-après les codes nécessaires vous permettant de compléter les rubriques figurant en en-tête de votre copie.

Ces codes doivent être reportés sur chacune des copies que vous remettrez.

BACKGROUND
Advances in lab automation and completion of the human genome project have resulted in the design of large-scale whole-genome libraries encompassing thousands of samples in a single run. These developments build on technological advances made by the pharmaceutical industry that required a need for screening large collections of chemical compounds in a very cost-effective manner and were subsequently adopted by academic institutions for chemical compound screening as well as expression cloning applications. Such large-scale screening approaches have enabled the unbiased identification of cell-based phenotypes and led to several ground-breaking discoveries, in particular for the identification of cell surface and virus receptors (Seed, 1995).

Expression cloning relies on the generation of an expressed cDNA library that can be transfected into target cells for assessment of changes in a cellular reporter activity or phenotype. Over the years, a complementary approach was developed based on the use of “antisense” constructs without a proper understanding of the underlying mechanisms. Eventually, after the discovery of RNA interference in the late 1990s and the development of mammalian siRNA libraries in the early 2000s, such knockdown technologies became mainstream for interrogating gene defects on a genome-wide scale. To date, siRNA genome-wide libraries are still the main application in genomic high-throughput screening, partially because of the lack of alternative methods. In recent years, many key problems of RNAi technology have become apparent, such as off-target effects, variable levels of knockdown efficiency and low-level confidence in hits of screening campaigns (Buehler et al., 2012; Marine et al., 2012). Hence, the siRNA screening community is openly discussing the need for alternative systems to overcome these limitations.

An alternative way of modifying the mammalian genome on a large-scale may lie in the use of genome editing technologies such as the use of targeted endonucleases. While zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALENs) are highly useful for gene editing, the cost and time to engineer the system makes it incompatible for the generation of large-scale whole-genome libraries. In particular, ZFN or TALEN require engineering of a protein component for each gene locus and this may not be amenable or cost-effective on a large-scale. With the CRISPR (clustered regularly interspaced short palindromic repeats)/Cas9 system, a cost-effective method that combines targeted genome editing with a simple, less time-consuming assay set-up is emerging and may be compatible with high-throughput screening approaches. An overview of the main techniques for genome editing and gene silencing is given in Table 1 and a detailed assessment of the advantages and disadvantages of genome editing methods has been given elsewhere (Ramalingam et al., 2013).

CRISPR/Cas9
The CRISPR/Cas9 system, originally exploited from Streptococcus pyogenes, is a general bacterial host defense mechanism to detect and degrade exogenous sequences from invading bacteriophages (Sorek et al., 2013). Short segments of foreign DNA are processed by CRISPR-associated (Cas) proteins into small elements which are then inserted into the CRISPR locus. RNAs from the CRISPR loci are constitutively transcribed and processed into small RNAs (crRNA) of exogenously derived DNA. These small RNAs then guide other Cas proteins such as Cas9 to mediate sequence-specific degradation of the foreign DNA. As such, the system serves two critical functions of acquired immunity, memory and pathogen elimination, and has some resemblance with acquired immunity in higher organisms. This system relies on the DNA endonuclease Cas9 that is targeted to a specific region of the genome to direct cleavage of the DNA in a sequence-specific manner (Jinek et al., 2012). Binding of Cas9 to the DNA is mediated by a partially complementary trans-acting RNA (tracrRNA) and cleavage is directed...

| **Genome editing**          |                                                                             |                                                                                      |                                                                                                |                                                        |
| Zinc finger nucleases (ZFNs)| Fok1 restriction nuclease fused to multiple zinc finger peptides; each targeting 3 bp of genomic sequence | Induces double-strand breaks in target DNA                                           | Can have off-target effects                                                                   | No – requires customization of protein component for each gene                                             |
| Transcription activator-like effector nucleases (TALENs) | Non-specific DNA-cleaving nuclease fused to a DNA-binding domain specific for a genomic locus | Induces double-strand breaks in target DNA                                           | Highly specific                                                                                | Feasible, but technically challenging (Reyon et al., 2012)                                               |
| Homing meganucleases       | Endonuclease with a large recognition site for DNA (12–40 base pairs)     | Induces double-strand breaks in target DNA                                           | Highly specific                                                                                | No – limited target sequence specificity available                                                         |
| CRISPR/Cas                 | 20 nt crRNA fused to tracrRNA and Cas9 endonuclease                         | Induces double-strand breaks in target DNA                                           | Some off-target effects that can be minimized by selection of unique crRNA sequences           | Yes – requires simple adapter cloning of 20 nt Oligos targeting each gene into a plasmid                   |
| **Gene silencing**         |                                                                             |                                                                                      |                                                                                                |                                                        |
| Post-transcriptional gene silencing (e.g., RNA interference) | Double-stranded RNA                                                          | DICER-mediated mRNA degradation; (post-transcriptional) | Can have significant off-target effects                                                       | Yes (Moffat et al., 2006)                                                                                  |
| Morpholino oligonucleotides | Synthetic oligonucleotide analogs                                          | Sterical blocking of translation initiation complex; (post-transcriptional)          | Can have significant off-target effects                                                       | Feasible, but technically challenging                                                                     |
| CRISPRi                     | sgRNA and catalytically inactive Cas9                                        | Transcriptional repression of RNA synthesis                                           | To be determined                                                                                | Yes                                                                                                    |

by a mature CRISPR RNA (crRNA; Deltcheva et al., 2011; Jinek et al., 2012). These three components, the Cas endonuclease, the tracrRNA, and crRNA are the basic constituents of this genome editing system.

By modifying these basic constituents for the use in other organisms, the CRISPR/Cas9 system has been shown to be a useful tool for gene editing and silencing. CRISPR sequences can be engineered which give rise to crRNA directed against specific endogenous genes in various organisms. Significant advances for the use of this technique have been promoted by the generation of a "single-guide RNA" (sgRNA) that combines the function of the tracrRNA and crRNA in a chimeric molecule (Jinek et al., 2012, 2013). By now the CRISPR/Cas9 system has been successfully used to target genomic loci in mammalian cell lines (Cho et al., 2013; Cong et al., 2013; Mali et al., 2013; Wang et al., 2013), zebrafish (Chang et al., 2013; Hwang et al., 2013), fungi (Dicalro et al., 2013), bacteria (jiang et al., 2013; Mali et al., 2013), C. elegans (Friedland et al., 2013), Drosophila (Gratz et al., 2013), plants (Li et al., 2013b; Nekrasov et al., 2013; Shan et al., 2013), rats (Li et al., 2013a,c), and mice (Wang et al., 2013). For instance, gene knockout mice can be rapidly generated when the desired gene locus is targeted via CRISPR/Cas9 (Wang et al., 2013). Quite importantly, multiple loci can be targeted at the same time by incorporation of multiple crRNA sequences (Cho et al., 2013; Wang et al., 2013). In zebrafish, where RNAi-based methods have limited capability, the use of CRISPR has enabled the generation of whole animals deficient in multiple gene loci (Chang et al., 2013; Hwang et al., 2013). The same system has been used to site-specifically insert mloxP sites, making it a novel reverse genetic tool for genome modification (Chang et al., 2013). In zebrafish and Drosophila it has been shown that CRISPR/Cas9 genome editing is inheritable with germline transmission reaching nearly 100% (Basset et al., 2013; Hwang et al., 2013; Yu et al., 2013).

Up to date three different versions of the Cas9 component have been described for the use in mammalian cells.

(A) Wild-type humanized (h)Cas9: Wild-type Cas9 will introduce a double-strand break (DSB) at the region it is targeted to, thus resulting in activation of the DSB repair machinery. Consequently, this will lead to insertion or deletion of nucleotides
at the site of injury of the DSB and lead to alterations in the DNA sequence and ultimately in gene expression.

(B) hCas9 D10A nickase: The wild-type endonuclease activity of Cas9 may, however, result in genome rearrangements that can lead to deleterious effects, e.g., selection against cells expressing wild-type Cas9 was observed (Qi et al., 2013). Furthermore, the generation of insertion/deletions (indels) at the target region as a consequence of DSB repair may lead to unwanted side-effects (Ketteler, 2012). To avoid those effects, Cong et al. used a mutant Cas9 nickase that only generates a nick in the genomic DNA at the target region, which in turn is repaired through high-fidelity homology-directed repair, rather than the error-prone Cas9 endonuclease-mediated non-homologous end-joining repair (Cong et al., 2013). The experiments to date suggest that this mutant Cas9 nickase shows similar targeting efficiencies compared to wild-type Cas9. Another advantage of the nickase system is that it can be used for generating knockout as well as knockin genotypes. This can be achieved by co-transfection of a recombination cassette with 5′- and 3′-flanking homology regions. However, knockout/knockin constructs based on the Cas9 nickase system require engineering of homologous recombination cassettes for each gene locus, thus making it technically challenging to implement on a large-scale.

(C) Catalytically dead dCas9: Qi et al. (2013) took a step further to generate a catalytically dead Cas9 lacking endonuclease activity. This resulted in gene silencing rather than gene editing of the target locus. This offers a significant advantage over classic RNAi-based silencing since mRNA synthesis is altered at an early stage of transcription by blocking RNA polymerase and transcript elongation whereas in RNA interference, the expressed synthesized mRNA is degraded. With this novel system, termed CRISPRi, the promoter region can also be targeted to efficiently knock down expression of the transcript. Moreover, Qi et al. (2013) showed that CRISPRi can be used to simultaneously repress multiple target genes (similar to chimeric hairpin constructs in RNAi, Gil-Humanes et al., 2010), which opens new strategies for large-scale profiling of genetic interactions in mammalian cells. The CRISPRi has enormous potential for gene silencing applications. Recently, it was shown that catalytic dead Cas9 can be fused to a general repressor or activator protein such as KRAB or VP16, respectively, shown that catalytic dead Cas9 can be fused to a general repressor or activator protein such as KRAB or VP16, respectively, which currently restricts the target efficiency of Cas9 to be addressed to enable the generation of large-scale CRISPR (crRNA) libraries.

**HIGH-THROUGHPUT SCREENING USING CRISPR/Cas9**

Recent improvements have enabled the use of the CRISPR/Cas9 system as a novel tool to manipulate specific genomic regions. These developments have prompted the proposal to use this technology to set-up high-throughput screening approaches analogous to siRNA-mediated large-scale screening experiments (Qi et al., 2013). Next, we would like to consider some aspects that need to be addressed in order to implement this technology on a large scale.

**DESIGN**

Several possible configurations of the CRISPR/Cas9 system exist (see Figure 1). The most striking advantage for all of them is the simplicity by which a gene can be targeted. Two main components are required: first, a codon-optimized version of Cas9 endonuclease and second, the RNA components crRNA and tracrRNA. The DNA sequence encoding the crRNA has a length of about 20 nucleotides and is also known as protospacer. At the 3′ end the crRNA sequence must finish with a 2 bp (base pair) protospacer adjacent motif (PAM) of the sequence GG or AG. The crRNA sequence can be designed as complementary to the + or − strand of the target DNA region. As mentioned before it is possible to combine the crRNA sequence with the tracrRNA sequence in a sgRNA. Also CRISPR vectors for the expression of sgRNA and Cas9 from a single plasmid can be obtained from various sources via Addgene 1. The generation of a genomic library for genome editing (using wild-type Cas9 or Cas9 nickase) or gene silencing (using catalytic inactive Cas9) can be achieved by a simple cloning of short DNA oligonucleotides into the respective CRISPR vectors. Protocols for plasmid construction and sub-cloning are freely available 2,3. Protocols for automation of such cloning on a large-scale have previously been developed and applied to the generation of genome-wide shRNA libraries (Moffat et al., 2006). Briefly, synthesized oligonucleotide pairs coding for the desired crRNA can be annealed separately and ligated into the CRISPR vector. The ligation can be transformed into competent bacteria in a 96-well plate format. The resulting transformations from one plate can be pooled and plated onto an agar plate for robotic colony picking and plasmid sequencing. This process showed a remarkable efficiency when applied to the generation of genome-wide shRNA libraries (Moffat et al., 2006).

It should be noted that other Cas family members and Cas proteins from other organisms than Streptococcus pyogenes may also be suitable for gene editing purposes. This can have significant advantages in the selection of the target sequence as some Cas endonucleases have different requirements with regards to the PAM motif, which currently restricts the target efficiency of Cas9

3. http://www.genome-engineering.org/crispr/?page_id=23
Accordingly, it was estimated that 1/8 of the genome hosts such incorporation into the sgRNA (Dicarlo et al., 2013; Mali et al., 2013). It has been observed to be variable and dependent on the cell type, as the PAM motif might be used to a lesser extent as well (Jiang et al., 2013). The main restriction for the design of sgRNA sequences is the GG-PAM. There is strong selection for a GG motif, while the AG sequence, a2b p(base pair) protospacer adjacent motif (PAM – green box) of the sequence GG is essential, but AG may be used to a lesser extend as well. A 12 bp seed region (blue box) at the 3′-end is required for sequence targeting with additional 8 bp at the 5′-end contributing to specificity (red box). sgRNA expression can be driven by a U6 promoter or alternatively by a H1 promoter. The Cas9 component is currently available in three different forms: as a wild-type (hCas9) or a mutant (D10A) version for gene editing purposes and a catalytically dead (dCas9) version for gene silencing approaches. Expression of Cas9 can be driven by any mammalian expression promoter (e.g., EF1A, CMV, etc.) or retroviral promoter (LTR). For nuclear targeting, the Cas9 gene requires multiple nuclear localization signals (NLS) and general expression of Cas9 can be enhanced by inclusion of a woodchuck post-transcriptional regulatory element (WPRE) at the 3′-end. A polyA-tail is required for expression vectors, while it should be deleted from lentiviral-representation vectors that have a polyA recognition sequence in their 3′-LTR. Variations of this design are possible with respect to the Cas gene used or further modifications such as tagging the Cas gene with GFP or NLSs in order to optimize Cas9 nuclear targeting.

FIGURE 1 | Design principle of a CRISPR/Cas9 expression vector for construction of large-scale libraries. The vector requires two minimal components, i.e., the single-guide RNA (sgRNA) sequence and the Cas9 gene that can both be expressed from a single-vector system. The sgRNA is composed of a variable crRNA and a constant tracrRNA. The gene sequence can be inserted by a simple adaptor cloning step in the 20 bp crRNA region. Furthermore, multiple target sequences of the same gene can be inserted to increase efficiency and reduce off-target effects. At the 3′-end of the crRNA sequence, a 2 bp (base pair) protospacer adjacent motif (PAM – green box) of the sequence GG is essential, but AG may be used to a lesser extent as well. A 12 bp seed region (blue box) at the 3′-end is required for sequence targeting with additional 8 bp at the 5′-end contributing to specificity (red box). sgRNA expression can be driven by a U6 promoter or alternatively by a H1 promoter. The Cas9 component is currently available in three different forms: as a wild-type (hCas9) or a mutant (D10A) version for gene editing purposes and a catalytically dead (dCas9) version for gene silencing approaches. Expression of Cas9 can be driven by any mammalian expression promoter (e.g., EF1A, CMV, etc.) or retroviral promoter (LTR). For nuclear targeting, the Cas9 gene requires multiple nuclear localization signals (NLS) and general expression of Cas9 can be enhanced by inclusion of a woodchuck post-transcriptional regulatory element (WPRE) at the 3′-end. A polyA-tail is required for expression vectors, while it should be deleted from lentiviral-representation vectors that have a polyA recognition sequence in their 3′-LTR. Variations of this design are possible with respect to the Cas gene used or further modifications such as tagging the Cas gene with GFP or NLSs in order to optimize Cas9 nuclear targeting.

to GG-PAM. For a review on sequence requirements of Cas proteins, please see Biswas et al., 2013. Furthermore, improvement of Cas9 and sgRNA expression and assembly, sgRNA-5′ and 3′ modifications or nuclear targeting will readily allow for improved CRISPR efficiency.

COVERAGE
The main restriction for the design of sgRNA sequences is the PAM motif. There is strong selection for a GG motif, while the AG motif might be used to a lesser extent as well (Jiang et al., 2013). Accordingly, it was estimated that 1/8 of the genome hosts such a motif, thus enabling very high coverage of genetic regions. The Church lab has compiled a list of sites within the Saccharomyces cerevisiae and H. sapiens genome with regions suitable for incorporation into the sgRNA (Dicarlo et al., 2013; Mali et al., 2013). It was estimated that 40.5% exons of genes in the human genome have a perfect match to the Streptococcus pyogenes Cas9 PAM motif and ∼190,000 sgRNA-targetable sequences were identified in total (Mali et al., 2013). Using other Cas9 family members that target regions with different PAM motifs will enable a good coverage of the whole-genome. It still needs to be established how to select the best suitable sequence for each gene.

EFFICIENCY
The efficiency of gene silencing by various CRISPR/Cas9 systems has been observed to be variable and dependent on the cell type, as well as the guide RNA sequence. For instance, length and sequence complementarity of the crRNA as well as the position to which the crRNA binds within the gene locus, have been reported to affect silencing efficiency (Gilbert et al., 2013; Qi et al., 2013). Repression was inversely correlated with target distance to the transcription start site. Mali et al. observed a targeting efficiency of 10–25% in 293T cells, 13–38% in K562 cells, and 2–4% in induced pluripotent stem cells using wild-type Cas9 (Mali et al., 2013). Hwang et al. (2013) achieved a targeting efficiency of >80% in zebrafish. The CRISPRi system using catalytically inactive Cas9 achieved efficiencies of gene silencing of 46–63% in HEK293 cells and much higher in E. coli (Qi et al., 2013).

Overall, the efficiency of knockdown needs further improvement to about 70–80% in order to produce robust phenotypes. With improvements in transfection or lentiviral infection and expression protocols as well as sgRNA design principles, the outlook is quite promising that this will be possible. Further, the incorporation of a combination of multiple crRNA sequences into each construct might be a possibility to enhance the efficiency of knockdown.

OFF-TARGET EFFECTS
The effect of off-target silencing has been evaluated in only a few examples. The minimal length of the base-pairing region within the crRNA is 12 bp (“seed region”), which can in some cases lead to significant binding to other regions of the genome. A recent study suggests that CRISPR-based genome editing has more off-target effects than other genome editing tools such as TALENs or ZFNs.
Another study that addressed the off-target effects of CRISPRi-Chang, N., Sun, C., Gao, L., Zhu, Buehler, E., Khan, A. A., Marine, October 2013 | Volume 4 | Article 193 |

DELIVERY

The combination of both Cas9 endonuclease and the sgRNA in one plasmid construct enables the use of single plasmid transfection into most standard cell lines. For primary cells, specialized protocols can even enable the generation of whole organism-based screening purposes. An alternative is the use of retroviral vector transduction, although one should keep in mind that there are biosafety considerations and extra care must be taken when handling humanized Cas9 endonuclease expression constructs. The use of short-term selection such as puromycin treatment can be included to enhance selection for stronger phenotypes (Wang et al., 2013). Longer selection and differentiation protocols can even enable the generation of whole organism-based silencing effects, for instance in zebrafish or mice (Hwang et al., 2013; Wang et al., 2013).

CONCLUSION

In conclusion, the design of a whole-genome targeted sgRNA library is feasible provided that CRISPR/Cas components are further optimized to ensure high-confidence genome engineering. Clearly, more data will be generated in the coming months to evaluate carefully off-target effects and sequence requirements for efficient gene knockdown. Also, the assessment of other Cas9 proteins for genome editing and silencing will be an important step forward. It should be noted that gene knockout of essential genes may result in lethality effects, thus making the analysis of more subtle phenotypes difficult. In those cases, silencing strategies such as RNAi-mediated knockdown or CRISPRi-mediated gene repression may be beneficial. Overall, given the simplicity of use developments need to be encouraged for the design of CRISPR/Cas-based large-scale whole-genome loss-of-function screening applications. Current RNAi libraries are limited to three model organisms, i.e., human, rat, and mouse. Since CRISPR gene silencing works very well in multiple model organisms, the development of libraries for other model organisms should be particularly encouraged.

INTRODUCTION

Duchenne muscular dystrophy (DMD) is an X-linked recessive disease caused by mutations in the gene coding for dystrophin, which is a large cytoskeletal protein essential for the integrity of muscle cell membranes. Dilated cardiomyopathy is one of the most common lethal features of the disease. We deployed Cpf1, a unique class 2 CRISPR (clustered regularly interspaced short palindromic repeats) effector, to correct DMD mutations in patient-derived induced pluripotent stem cells (iPSCs) and mdx mice, an animal model of DMD. Cpf1-mediated genomic editing of human iPSCs, either by skipping of an out-of-frame DMD exon or by correcting a nonsense mutation, restored dystrophin expression after differentiation to cardiomyocytes and enhanced contractile function. Similarly, pathophysiological hallmarks of muscular dystrophy were corrected in mdx mice following Cpf1-mediated germline editing. These findings are the first to show the efficiency of Cpf1-mediated correction of genetic mutations in human cells and an animal disease model and represent a significant step toward therapeutic translation of gene editing for correction of DMD.

RESULTS

Correction of DMD iPSC-derived cardiomyocytes by Cpf1-mediated genome editing

Exon deletions preceding exon 51 of the human DMD gene, which disrupt the open reading frame (ORF) by juxtaposing out-of-frame exons, represent the most common type of human DMD mutation (24). Skipping of exon 51 can, in principle, restore the DMD ORF in 13% of DMD patients with exon deletions (25). To test the potential of Cpf1

to correct this type of “hotspot” mutation, we used DMD patient fibroblast-derived induced pluripotent stem cells (iPSCs) (Riken HPS0164; abbreviated as Riken51), which harbor a deletion of exons 48 to 50, introducing a premature termination codon within exon 51 (Fig. 1A).

The splice acceptor region is generally pyrimidine-rich (26), which creates an ideal PAM sequence for genome editing by Cpf1 endonuclease (Fig. 1B). To rescue dystrophin expression in Riken51 iPSCs, we used a Cpf1 gRNA to target exon 51, introducing small insertions and deletions (INDELs) in exon 51 by NHEJ and subsequently reframing the dystrophin ORF, theoretically, in one-third of corrected genes, a process we refer to as “reframing” (Fig. 1A). We also compared two Cpf1 orthologs, LbCpf1 (from Lachnospiraceae bacterium ND2006) and AsCpf1 (from Acidaminococcus sp. BV3L6), which use the same PAM sequences for genome cleavage.

Cpf1 cleavage was targeted near the T-rich splice acceptor site of exon 51 using a gRNA (designated g1) (Fig. 1C), which was cloned into the plBcPf1-2A-GFP and pAsCpf1-2A-GFP plasmids (Fig. 1D). These plasmids express human codon-optimized LbCpf1 or AsCpf1, plus green fluorescent protein (GFP), enabling fluorescence-activated cell sorting (FACS) of Cpf1-expressing cells (Fig. 1D). Initially, we evaluated the cleavage efficiency of Cpf1 editing with g1 in human 293T cells. Both LbCpf1 and AsCpf1 efficiently induced DNA cleavage with g1, as detected using the T7E1 assay that recognizes and cleaves nonperfectly matched DNA (Fig. 1E).

Next, we used LbCpf1 and AsCpf1 with g1 to edit Riken51 iPSCs, and using the T7E1 assay, we observed genome cleavage at DMD exon 51 (Fig. 1E). Genomic polymerase chain reaction (PCR) products from the Cpf1–edited DMD exon 51 were cloned and sequenced (fig. S1A). We observed INDELs near the exon 51 splice acceptor site in both LbCpf1– and AsCpf1–edited Riken51 iPSCs (fig. S1A). Single clones from a mixture of reframed Riken51 iPSCs were picked and expanded, and the edited genomic region was sequenced. Of the 12 clones, we observed 4 clones with reframed DMD exon 51, which restored the ORF (fig. S1B).

**Restoration of dystrophin expression in DMD iPSC-derived cardiomyocytes after Cpf1-mediated reframing**

Riken51 iPSCs edited by CRISPR–Cpf1 using the reframing strategy were induced to differentiate into cardiomyocytes (Fig. 2A) (27). Cardiomyocytes with the reframed DMD gene were identified by reverse transcription PCR (RT-PCR) using a forward primer targeting exon 47 and a reverse primer targeting exon 52, and the PCR products were sequenced (Fig. 2, B and C). Uncorrected iPSC-derived cardiomyocytes have a premature termination codon following the first eight amino acids encoded by exon 51 (Fig. 2C). Cardiomyocytes differentiated from Cpf1–edited Riken51 iPSCs showed restoration of the DMD ORF, as seen by sequencing of the RT-PCR products from amplification of exons 47 to 52 (Fig. 2C). We also confirmed restoration of dystrophin protein expression by Western blot analysis and immunocytochemistry using a dystrophin antibody (Fig. 2, D and E). Even without clonal selection and expansion, cardiomyocytes differentiated from Cpf1–edited iPSC mixtures showed levels of dystrophin protein comparable to wild-type (WT) cardiomyocytes (Fig. 2D).

From mixtures of LbCpf1–edited Riken51 iPSCs, we picked two clones (clones #2 and #5) with in-frame INDELs of different sizes and differentiated the clones into cardiomyocytes. Clone #2 had an 8-bp deletion at the 5′ end of exon 51, together with an endogenous deletion of exons 48 to 50. The total 405-bp deletion restored the DMD

---

*Fig. 1. Correction of DMD mutations by Cpf1-mediated genome editing. (A) A DMD deletion of exons 48 to 50 results in splicing of exons 47 to 52, generating an out-of-frame mutation of dystrophin. Two strategies were used for the restoration of dystrophin expression by Cpf1. In the “reframing” strategy, small INDELs in exon 51 restore the protein reading frame of dystrophin. Two strategies were used for the restoration of dystrophin expression by Cpf1. In the “reframing” strategy, small INDELs in exon 51 restore the protein reading frame of dystrophin. (B) The 3′ end of an intron is T-rich, which generates Cpf1 PAM sequences, enabling genome cleavage by Cpf1. (C) Illustration of Cpf1 gRNA targeting DMD exon 51. The T-rich PAM (red line) is located upstream of exon 51 near the splice acceptor site. The sequence of the Cpf1 g1 gRNA targeting exon 51 is shown, highlighting the complementary nucleotides in blue. Cpf1 cleavage produces a staggered end distal to the PAM site (demarcated by red arrowheads). The 5′ region of exon 51 is shaded in light blue. Exon sequence is in uppercase letters, Intron sequence is in lowercase letters. (D) Illustration of a plasmid encoding human codon-optimized Cpf1 (hCpf1) with a nuclear localization signal (NLS) and 2A–GFP, driven by a hybrid form of cytomegalovirus and chicken β-actin promoters (CBh). The plasmid also encodes a Cpf1 gRNA driven by the U6 promoter. Cells transfected with this plasmid express GFP, allowing for selection of Cpf1-expressing cells by FACS. (E) T7E1 assays using human 293T cells or DMD iPSCs (Riken51) transfected with plasmid expressing LbCpf1 or AsCpf1, gRNA, and GFP show genome cleavage at DMD exon 51. Red arrowheads point to cleavage products. M, marker; bp, base pair.*
Fig. 2. DMD iPSC-derived cardiomyocytes express dystrophin after Cpf1-mediated genome editing by reframing. (A) DMD skin fibroblast-derived iPSCs were edited by Cpf1 using gRNA (corrected DMD iPSCs) and then differentiated into cardiomyocytes (corrected cardiomyocytes) for analysis of genetic correction of the DMD mutation. (B) A DMD deletion of exons 48 to 50 results in splicing of exon 47 to 51, generating an out-of-frame mutation of dystrophin. Forward primer (F) targeting exon 47 and reverse primer (R) targeting exon 52 were used in RT-PCR to confirm the reframing strategy by Cpf1-mediated genome editing in cardiomyocytes. Uncorrected cardiomyocytes lack exons 48 to 50. In contrast, after reframing, exon 51 is placed back in frame with exon 47. (C) Sequencing of representative RT-PCR products shows that uncorrected DMD iPSC-derived cardiomyocytes have a premature stop codon in exon 51, which creates a nonsense mutation. After Cpf1-mediated reframing, the ORF of dystrophin is restored. Dashed red line denotes exon boundary. (D) Western blot analysis shows dystrophin expression in a mixture of DMD iPSC-derived cardiomyocytes edited by reframing with LbCpf1 or AsCpf1 and g1 gRNA. Even without clonal selection, Cpf1-mediated reframing is efficient and sufficient to restore dystrophin expression in the cardiomyocyte mixture. α-Myosin heavy chain (αMHC) is loading control. (E) Immunocytochemistry shows dystrophin expression in iPSC-derived cardiomyocyte (CM) mixtures following LbCpf1- or AsCpf1-mediated reframing. Red, dystrophin staining; green, troponin I staining. Scale bar, 100 μm. (F) Western blot analysis shows dystrophin expression in single clones (#2 and #5) of iPSC-derived cardiomyocytes following clonal selection after LbCpf1-mediated reframing. αMHC is loading control. (G) Immunocytochemistry shows dystrophin expression in clone #2 LbCpf1-edited iPSC-derived cardiomyocytes. Scale bar, 100 μm. (H) Quantification of mtDNA copy number in single clones (#2 and #5) of LbCpf1-edited iPSC-derived cardiomyocytes. Data are means ± SEM (n = 3). *P < 0.05, **P < 0.01, and ***P < 0.005. ns, not significant. (I) Basal OCR of single clones (#2 and #5) of LbCpf1-edited iPSC-derived cardiomyocytes, and OCR in response to oligomycin, FCCP, rotenone, and antimycin A, normalized to cell number. Data are means ± SEM (n = 5). *P < 0.05, **P < 0.01, and ***P < 0.005.
ORF and allowed for the production of a truncated dystrophin protein with a 135–amino acid deletion. Clone #5 had a 17-bp deletion in exon 51 and produced dystrophin protein with a 138–amino acid deletion. Although there is high efficiency of cleavage by Cpf1, the amount of DNA inserted or deleted at the cleavage site varies. Additionally, INDELS can generate extra codons at the edited locus, causing changes of the ORF. The dystrophin protein expressed by clone #2 cardiomyocytes generated an additional four amino acids (Leu-Leu-Leu-Arg) between exon 47 and exon 51, whereas dystrophin protein expressed by clone #5 cardiomyocytes generated only one additional amino acid (Leu). From both clones #2 and #5, we observed restored dystrophin protein by Western blot analysis and immunocytochemistry (Fig. 2, F and G). Because of the large size of dystrophin, the internally deleted forms migrated similarly to WT dystrophin on SDS–polyacrylamide gel electrophoresis.

We also performed functional analysis of DMD iPSC-derived cardiomyocytes by measuring mitochondrial DNA (mtDNA) copy number and cellular respiration rates. Uncorrected DMD iPSC-derived cardiomyocytes had significantly fewer mitochondria than the LbCpf1-corrected cardiomyocytes (Fig. 2H). After LbCpf1-mediated reframing, both corrected clones restored mitochondrial number to a level comparable to that of WT cardiomyocytes (Fig. 2H). Clone #2 iPSC-derived cardiomyocytes also showed an increase in oxygen consumption rate (OCR) compared to uncorrected iPSC-derived cardiomyocytes at baseline (Fig. 2I). OCR was inhibited by oligomycin in all iPSC-derived cardiomyocytes, and treatment with the uncoupling agent FCCP (carbonyl cyanide p-trifluoromethoxyphenylhydrazone) enhanced OCR. Finally, treatment with rotenone and antimycin A further inhibited OCR in all cardiomyocytes. These results demonstrate that Cpf1-mediated DMD correction improved respiratory capacity of mitochondria in corrected iPSC-derived cardiomyocytes. Our findings show that Cpf1-mediated reframing is a highly efficient strategy to rescue DMD phenotypes in human cardiomyocytes.

**Restoration of dystrophin expression in DMD iPSC-derived cardiomyocytes by Cpf1-mediated exon skipping**

In contrast to the single gRNA-mediated reframing method, which introduces small INDELS, exon skipping uses two gRNAs to disrupt splice sites and generates a large deletion (Fig. 3A). As an independent strategy to restore dystrophin expression in the Riken51 iPSCs, we designed two LbCpf1 gRNAs (g2 and g3) that target the 3′ end of intron 50 and test the cleavage efficiency in human 293T cells. The T7E1 assay showed that g2 had higher cleavage efficiency within intron 50 compared to g3 (Fig. 3B). Therefore, we co-delivered LbCpf1, g2, and g1 (g1 targets the 5′ region of exon 51) into Riken51 iPSCs, with the aim of disrupting the splice acceptor site of exon 51. Genomic PCR showed a lower band in LbCpf1-edited iPSCs (Fig. 3C), and sequencing data confirmed the presence of a deletion of ~200 bp between intron 50 and exon 51, which disrupted the conserved splice acceptor site (Fig. 3D).

Targeting specificity of Cpf1 was evaluated using the top 10 potential genome-wide off-target sites (OT-01 to OT-10) for each gRNA, as predicted by Cas-Offinder (www.rgenome.net/cas-offinder/) (tables S1 and S2). Efficient cleavage bands were observed at the on-target site, and most of the off-target sites did not show a detectable cleavage band by the T7E1 assay (fig. S2). Efficient cleavage bands were observed at the on-target site, determined by Cas-OFFinder (www.rgenome.net/cas-offinder/) (tables S1 and S2). Efficient cleavage bands were observed at the on-target site.

Riken51 iPSCs edited by the exon skipping strategy with g1 and g2 were differentiated into cardiomyocytes. Cells harboring the edited DMD allele were identified by RT-PCR using a forward primer targeting exons 47 and a reverse primer targeting exon 52, showing deletion of the exon.
51 splice acceptor site, which allows skipping of exon 51 (Fig. 3E). Sequencing of the RT-PCR products confirmed that exon 47 was spliced to exon 52, which restored the DMD ORF (Fig. 3F). Western blot analysis and immunocytochemistry confirmed the restoration of dystrophin protein expression in a mixture of LbcPcf1-edited cardiomyocytes with g1 and g2 (Fig. 3, G and H). Thus, Cpf1 editing by the exon skipping strategy is highly efficient in rescuing the DMD phenotype in human cardiomyocytes.

Restoration of dystrophin in mdx mice by Cpf1-mediated correction
To further evaluate the potential of Cpf1-mediated Dmd correction in vivo, we used LbcPcf1 to permanently correct the mutation in the germ line of mdx mice by HDR-mediated correction or NHEJ-mediated re-framing. mdx mice carry a nonsense mutation in exon 23 of the Dmd gene because of a C-to-T transition (Fig. 4A). Three gRNAs (g1, g2, and g3) that target exon 23 were screened and tested in mouse 10T1/2 fibroblasts for cleavage efficiency (Fig. 4B). The T7E1 assay revealed that LbcPcf1 and AsCpf1 had different cleavage efficiencies at Dmd exon 23 (Fig. 4C). On the basis of sequencing results, LbcPcf1-mediated genome editing using g2 generated a greater occurrence of INDELS in mouse fibroblasts compared to g3 (fig. S1C).

LbcPcf1 editing with g2 recognizes a PAM sequence 9 bp upstream of the mutation site and creates a staggered double-stranded DNA cut 8 bp downstream of the mutation site (Fig. 4D). To obtain HDR genome editing, we used a 180-bp single-stranded oligodeoxynucleotide (ssODN) in combination with LbcPcf1 and g2, because it has been shown that ssODNs are more efficient in introducing small genomic modifications than double-stranded donor plasmids (6, 7). We generated an ssODN containing 90 bp of sequence homology flanking the cleavage site, including four silent mutations and a Tse I restriction site to facilitate genotyping, as previously described (7). This ssODN was designed to be used with LbcPcf1 and g2 to correct the C-to-T mutation within Dmd exon 23 and to restore dystrophin in mdx mice by HDR.

Correction of muscular dystrophy in mdx mice by LbcPcf1-mediated HDR or NHEJ
mdx zygotes were conjoined with in vitro transcribed LbcPcf1 mRNA, in vitro transcribed g2 gRNA, and 180-bp ssODN and reimplanted into pseudopregnant females (Fig. 5A). Three litters of LbcPcf1-edited mdx mice were analyzed by the T7E1 assay and Tse I RFLP (restriction fragment length polymorphisms) (Fig. 5, B and C). Of the 24 pups born, 12 were T7E1-positive and 5 carried corrected alleles (mdx-C1 to mdx-C5), as detected by Tse I RFLP and sequencing (Fig. 5, C and D). Skeletal muscles (tibialis anterior and gastrocnemius/plantaris) from WT, mdx, and LbcPcf1-corrected mdx-C mice were analyzed at 4 weeks of age. Hematoxylin and eosin (H&E) staining of muscle showed fibrosis and inflammatory infiltration in mdx muscle, whereas LbcPcf1-corrected (mdx-C) muscle displayed normal muscle morphology and no signs of a dystrophic phenotype (Fig. 5E and fig. S5, A and B). Immunohistochemistry showed the absence of dystrophin-positive fibers in muscle sections of mdx mice, whereas mdx-C muscle corrected by LbcPcf1-mediated HDR showed dystrophin protein expression in a majority of muscle fibers (Fig. 5F and fig. S5, A and B).

Additionally, we performed histological analysis of different tissues from multiple mdx-C mice with correction rates from 8 to 50%. All LbcPcf1-corrected mdx-C mice showed restored dystrophin expression in multiple tissues, including skeletal muscles, heart, and brain (figs. S6 and S7). Muscle of mdx-C mice with 50% genomic correction showed full restoration of dystrophin protein and displayed no sign of fibrosis or inflammatory infiltration, which is consistent with our previous study (7). Western blot analysis showed expression of dystrophin protein in multiple skeletal muscle groups, heart, and brain (fig. S8), consistent with percentages of dystrophin-positive fibers seen with immunohistochemistry (fig. S6).

LbcPcf1-mediated correction of the Dmd mutation in germ cells was evaluated in eggs and sperm of LbcPcf1-corrected mdx-C mice by T7E1 assays and Tse I RFLP. All LbcPcf1-corrected mdx-C mice carried a corrected allele in their germ cells (fig. S9). Genome editing efficiency...
Fig. 5. CRISPR-LbCpf1–mediated Dmd correction in mdx mice. (A) Strategy of gene correction in mdx mice by LbCpf1-mediated germline editing. Zygotes from intercrosses of mdx parents were injected with gene editing components (LbCpf1 mRNA, g2 gRNA, and ssODN) and reimplanted into pseudopregnant mothers, which gave rise to pups with gene correction (mdx-C). (B) Illustration showing LbCpf1 correction of mdx allele by HDR or NHEJ. (C) Genotyping results of LbCpf1-edited mdx mice. Top: T7E1 assay. Blue arrowhead denotes uncleaved DNA, and red arrowhead shows T7E1-cleaved DNA. Bottom: Tse I RFLP assay. Blue arrowhead denotes uncorrected DNA, and red arrowhead points to Tse I cleavage, indicating HDR correction. mdx-C1 to mdx-C5 denote LbCpf1-edited mdx mice. (D) Top: Sequence of WT Dmd exon 23. Middle: Sequence of mdx Dmd exon 23 with C-to-T mutation, which generates a stop codon. Bottom: Sequence of Dmd exon 23 with HDR correction by LbCpf1-mediated editing. Black arrows point to silent mutations introduced by the ssODN HDR template. (E) H&E staining of tibialis anterior (TA) and gastrocnemius/plantaris (G/P) muscles from WT, mdx, and LbCpf1-edited mice (mdx-C). Scale bar, 100 μm. (F) Immunohistochemistry of tibialis anterior and gastrocnemius/plantaris muscles from WT, mdx, and LbCpf1-edited mice (mdx-C) using an antibody to dystrophin (red). mdx muscle showed fibrosis and inflammatory infiltration, whereas mdx-C muscle showed normal muscle structure.
of Cas9 and LbCpf1 was compared at the Dmd exon 23 locus, and no significant difference was observed (table S3).

Physiological and functional analyses were also performed in WT, mdx, and LbCpf1-corrected mdx-C mice. Serum creatine kinase (CK) levels were decreased substantially in mdx-C mice and were inversely correlated with the percentage of genome correction (Table 1). The forelimb grip strength test indicated that LbCpf1-corrected mdx-C mice had improved muscle strength compared to mdx mice (Table 1).

**DISCUSSION**

Here, we show that the newly discovered CRISPR-Cpf1 nuclease can efficiently correct DMD mutations in patient-derived iPSCs and mdx mice, allowing for restoration of dystrophin expression. Lack of dystrophin in DMD has been shown to disrupt the integrity of the sarcolemma, causing mitochondrial dysfunction and oxidative stress (28, 29). We found increased mtDNA and higher OCRs in LbCpf1-corrected iPSC-derived cardiomyocytes compared to uncorrected DMD iPSC-derived cardiomyocytes. Metabolic abnormalities of human DMD iPSC-derived cardiomyocytes were also rescued by Cpf1-mediated genomic editing. Our findings also demonstrated the robustness and efficiency of Cpf1 in mouse genome editing. By using HDR-mediated correction, the ORF of the mouse Dmd gene was completely restored, and pathophysiological hallmarks of the dystrophic phenotype, such as fibrosis and inflammatory infiltration, were also rescued.

Two different strategies—reframing and exon skipping—were applied to restore the ORF of the DMD gene using LbCpf1-mediated genome editing. Reframing creates small INDELs and restores the ORF by placing out-of-frame codons in frame. Only one gRNA is required for reframing. Although we did not observe any differences in subcellular localization between WT dystrophin protein and reframed dystrophin protein by immunocytochemistry, we observed differences in dystrophin expression level, mtDNA quantity, and OCR in different edited clones, suggesting that reframed dystrophin may not be structurally or functionally identical to WT dystrophin.

Various issues should be considered with respect to the use of one or two gRNAs with Cpf1 editing. Here, we show that two gRNAs are more effective than one gRNA for disruption of the splice acceptor site compared to reframing. When using two gRNAs, Cpf1 editing excises the intervening region and not only removes the splice acceptor site but also can be designed to remove deleterious "AG" nucleotides, eliminating the possibility of generating a pseudosplice acceptor site. However, with two gRNAs, there is the necessity that both gRNAs cleave simultaneously, which may not occur. If only one of the two gRNAs cleaves, the desired deletion will not be generated. However, there remains the possibility that cleavage with one of the two gRNAs will generate INDELs at the targeted exon region, reframing the ORF, because in theory, one-third of the INDELs will be in frame. Using one gRNA to disrupt the splice acceptor site seems more efficient because it eliminates the need for two simultaneous cuts to occur. However, there is uncertainty with respect to the length of the INDEL generated by one gRNA-mediated

Table 1. Serum CK measurement and forelimb grip strength of WT, mdx, and LbCpf1-corrected mdx-C mice. M, male; F, female.
editing. With one gRNA, there remains the possibility of leaving exonic AG nucleotides near the cleavage site, which can serve as an alternative pseudosplice acceptor site.

With its unique T-rich PAM sequence, Cpf1 further expands the genome editing range of the CRISPR family, which is important for potential correction of other disease-related mutations because not all mutation sites contain G-rich PAM sequences for SpCas9 or PAMs for other Cas9 orthologs. Moreover, the staggered cut generated by Cpf1 may also be advantageous for NHEJ-mediated genome editing (30). Finally, the LbCpf1 used in this study is 140 amino acids smaller than the most widely used SpCas9, which would enhance packaging and delivery by AAV.

Our off-target analysis by T7E1 assays and quantitative capillary electrophoresis using a fragment analyzer showed similar results to previous reports (16, 17), indicating that LbCpf1 and AsCpf1 had high genome-wide targeting efficiency and high specificity comparable to those of SpCas9. This is reflective of LbCpf1 and AsCpf1 not tolerating mismatches at the PAM proximal region, thereby lessening the frequency of off-targeting effect.

Our findings show that Cpf1 is highly efficient in correcting human DMD and mouse Dmd mutations in vitro and in vivo. CRISPR-Cpf1–mediated genome editing represents a new and powerful approach to permanently eliminate genetic mutations and rescue abnormalities associated with DMD and other disorders.

MATERIALS AND METHODS

Generation of pLBcPf1-2A-GFP and pAsCpf1-2A-GFP plasmids

Human codon-optimized LbCpf1 and AsCpf1 were PCR-amplified from the pY016 plasmid (14) (pcDNA3.1-hLbCpf1), a gift from F. Zhang (Addgene plasmid #69988), and the pY010 plasmid (14) (pcDNA3.1-hAsCpf1), a gift from F. Zhang (Addgene plasmid #69982), respectively. Cpf1 complementary DNA (cDNA) and T2A-GFP DNA fragment were cloned into the backbone of the pSpCas9(BB)-2A-GFP (PX458) plasmid (13), a gift from F. Zhang (Addgene plasmid #48138), which was cut with AgeI/EcoRI to remove SpCas9(BB)-2A-GFP. In-Fusion HD Cloning Kit (Takara Bio) was used. Cpf1 gRNAs targeting the human DMD or the mouse Dmd locus were subcloned into newly generated pLbCpf1-2A-GFP and pAsCpf1-2A-GFP plasmids using BbsI digestion and T4 ligation. Detailed primer sequences can be found in the Supplementary Materials (table S4).

Human iPSC maintenance, nucleofection, and differentiation

Human iPSCs (RBRC-HPS0164) were purchased from Cell Bank RIKEN BioResource Center. Human iPSCs were cultured in mTeSR1 medium (STEMCELL Technologies) and passaged approximately every 4 days (1:18 split ratio). One hour before nucleofection, iPSCs were treated with 10 μM ROCK inhibitor (Y-27632) and dissociated into single cells using Accutase (Innovative Cell Technologies Inc.). iPSCs (1×10^6) were mixed with 5 μg of the pLBcPf1-2A-GFP or pAsCpf1-2A-GFP plasmid and nucleofected using the P3 Primary Cell 4D-Nucleofector X Kit (Lonza) according to the manufacturer’s protocol. After nucleofection, iPSCs were picked and sequenced. iPSCs were induced to differentiate into cardiomyocytes, as previously described (27).

Genomic DNA isolation

Genomic DNA of mouse 10T1/2 fibroblasts and human iPSCs was isolated using a Quick-gDNA MiniPrep kit (Zymo Research) according to the manufacturer’s protocol.

Reverse transcription PCR

RNA was isolated using TRizol (Thermo Fisher Scientific) according to the manufacturer’s protocol. cDNA was synthesized using the iScript Reverse Transcription Supermix (Bio-Rad Laboratories) according to the manufacturer’s protocol. RT-PCR was performed using primers flanking DMD exons 47 and 52 (forward, 5′-CCCCAGAAGAGCAGAATCCTCTGAA-3′; reverse, 5′-CTCTGGTCCAAATCTGGTTC-3′). RT-PCR products amplified from WT cardiomyocytes, uncorrected cardiomyocytes, and exon 51–skipped cardiomyocytes were picked and sequenced. iPSCs were induced to differentiate into cardiomyocytes, as previously described (27).

Dystrophin Western blot analysis

Western blot analysis for human iPSC-derived cardiomyocytes was performed, as previously described (7), using a rabbit anti-dystrophin antibody (Abcam, ab15277) and a mouse anti-cardiac myosin heavy chain antibody (Abcam, ab50967). For mouse skeletal muscles, heart, and brain, the Western blot was performed, as previously described (7), using a mouse anti-dystrophin antibody (Sigma-Aldrich, D8168) and a mouse anti-vinculin antibody (Sigma-Aldrich, V9131).

Dystrophin immunocytochemistry and immunohistochemistry

iPSC-derived cardiomyocytes were fixed with acetone, blocked with serum cocktail [2% normal horse serum/2% normal donkey serum/0.2% bovine serum albumin (BSA)/phosphate-buffered saline (PBS)], and incubated with a dystrophin antibody (MANDYS8, 1:800; Sigma-Aldrich) and troponin I antibody (H170, 1:200; Vector Laboratories), and fluorescein-conjugated donkey anti-rabbit IgG, 1:50 (Jackson ImmunoResearch) for 1 hour. Nuclei were counterstained with Hoechst 33342 (Molecular Probes).

Immunohistochemistry of skeletal muscles, heart, and brain was performed, as previously described (7, 12), using a dystrophin antibody (MANDYS8, 1:800; Sigma-Aldrich). Nuclei were counterstained with Hoechst 33342 (Molecular Probes).

mtDNA copy number quantification

Genomic DNA and mtDNA were isolated using TRizol, followed by back extraction, as previously described (31). KAPA SYBR FAST qPCR Kit (Kapa Biosystems) was used to perform real-time PCR to quantitatively determine mtDNA copy number. Human mitochondrial ND1 gene was amplified using primers (forward, 5′-CGGCCACATCTACCATCACCCCTC-3′; reverse, 5′-CGGCCATAGCTAGAGGTCAGTACAT-3′). Human genomic LPL gene was amplified using primers (forward, 5′-GAGTGTCAAGAAGCGCAGGTC-3′; reverse, 5′-TCAACTCGTCGCTTTGCTG-3′). mtDNA copy number per diploid genome was calculated using the following formulas: ΔCt = (mtND1 Ct − LPL Ct) and mtDNA copy number per diploid genome = 2 × 2 ^ ΔCt.
In vitro transcription of LbCpf1 mRNA and gRNA
Human codon-optimized LbCpf1 was PCR-amplified from plLbCpf1-2A-GFP to include the T7 promoter sequence (table S4). The PCR product was transcribed using the mMESSAGE m_MACHINE T7 Transcription Kit (Thermo Fisher Scientific) according to the manufacturer’s protocol. Synthesized LbCpf1 mRNAs were polyadenylated [poly(A)]-tailed with E. coli Poly(A) Polymerase (New England Biolabs) and purified using NucAway spin columns (Thermo Fisher Scientific).

The template for LbCpf1 gRNA in vitro transcription was PCR-amplified from the plLbCpf1-2A-GFP plasmid and purified using the Wizard SV Gel and PCR Clean-Up System (Promega). The LbCpf1 gRNA was synthesized using the MEGAscript T7 Transcription Kit (Thermo Fisher Scientific) according to the manufacturer’s protocol. Synthesized LbCpf1 gRNA was purified using NucAway spin columns (Thermo Fisher Scientific).

Single-stranded oligodeoxynucleotide
ssODN was used as HDR template and synthesized by Integrated DNA Technologies as 4 nM Ultramer oligonucleotides. ssODN was mixed with LbCpf1 mRNA and gRNA directly without purification. The sequence of ssODN is as follows: 5′-TGATATGATGTTGATGAGTGGATCAATGCTCTGCAAAATGCGTGTTAGTGTAAATGAACTTCTATTTG-3′.

Cellular respiration rates
OCRs were determined in human iPSC-derived cardiomyocytes using the XF24 Extracellular Flux Analyzer (Seahorse Bioscience) following the manufacturer’s protocol, as previously described (32).

Mouse forelimb grip strength test and serum CK measurement
Grip strength test and serum CK measurement were performed, as previously described (7), by the Neuro-Models Core Facility and the Metabolic Phenotyping Core at the University of Texas Southwestern Medical Center, respectively.

Off-target site analysis
Off-target sites were predicted using Cas-OFFinder (http://www.cas-offinder.org/index.html) and off-target analysis was performed as previously described (12). Sequences are provided in the Supplementary Materials (tables S1 and S2). For capillary electrophoresis, PCR products from control and treated samples were denatured and reannealed to form heteroduplex. T7EI-digested DNA samples were visualized by the Fragment Analyzer (Advanced Analytical), which allowed a sensitive, accurate, and fast quantification of percent cleavage. The PCR sample (2 μl) was diluted with the sample buffer (DNF-910-1000CP CRISPR kit) and loaded into the 96-well sample plate. Cleavage percentage was calculated by CRISPR Plugin for PROSize 2.0. Expected full-length and cleavage fragment sizes of PCR samples were entered into the software. Highlighted fragments with automated scores were shown in figs. S3B and S4B. Concentration of each peak and cleavage value were automatically calculated by the software. Reconstructed gel images from the Fragment Analyzer electropherogram were shown in figs. S3A and S4A.

Statistical analysis
Statistical analysis was assessed by two-tailed Student’s t test. Data are shown as means ± SEM. A P < 0.05 value was considered statistically significant.
