Abstract. We study in this work a scenario that the universe undergoes a two step phase transition with the first step happened to the dark matter sector and the second step being the transition between the dark matter and the electroweak vacuums, where the barrier between the two vacuums, that is necessary for a strongly first order electroweak phase transition (EWPT) as required by the electroweak baryogenesis mechanism, arises at the tree-level. We illustrate this idea by working with the standard model (SM) augmented by a scalar singlet dark matter and an extra scalar singlet which mixes with the SM Higgs boson. We study the conditions for such pattern of phase transition to occur and especially for the strongly first order EWPT to take place, as well as its compatibility with the basic requirements of a successful dark matter, such as observed relic density and constraints of direct detections. We further explore the discovery possibility of this pattern EWPT by searching for the gravitational waves generated during this process in spaced based interferometer, by showing a representative benchmark point of the parameter space that the generated gravitational waves fall within the sensitivity of eLISA, DECIGO and BBO.

1 Introduction

The Standard Model (SM) of particle physics so far provides an excellent description of a wide variety of experimental observations, nevertheless, it must be extended because it fails at least in explaining two cosmological puzzles: it does not provide a dark matter (DM) candidate and it is not possible to generate the observed baryon asymmetry of the universe (BAU). The later one requires a strongly first order electroweak phase transition (EWPT) to provide a non-equilibrium environment if the BAU is generated via the electroweak baryogenesis mechanism [1–4]. Since the 125 GeV Higgs boson is too heavy to give rise to a first order EWPT [5, 6], new ingredients beyond the SM Higgs interactions may be needed. On the other hand, how DM interacts with the SM particles remains unknown. The Higgs portal turns to be attractive since it may kill two birds (DM and the strongly first order EWPT [7]) with one stone.

The characteristics of a scalar DM triggered strongly first order EWPT are twofold: (i) It is a two-step phase transition [8–14] and the barrier between electroweak symmetric and broken phases arises at the tree-level, which may avoid the problem of gauge-dependence [15]; (ii) The parameter space of the model is strongly constrained by the exclusion limits of direct detections and can not explain the observed relic density. It was pointed out in ref. [16] that, for the SM plus a real scalar DM $S$ scenario, $S$ could only constitute up to 3% of the total DM relic density, while still be relevant for the direct detection because of its sizable coupling with the SM Higgs as required by the two-step EWPT.

In this paper, we revisit this type of EWPT by extending the SM with a scalar singlet DM $S$ and another scalar singlet $\Phi$ which can mix with the SM-like Higgs boson. Due to the mixing of $\Phi$ with the SM Higgs, there are two separate contributions to DM nucleon scattering, which may cancel with each other and leads to a negligible cross section. It results in a mechanism to suppress the direct detection signal and evade the currently most stringent experimental constraints from the direct detection experiments [17–19]. Furthermore, the quartic interaction $\Phi^2 S^2$ may contribute to the mass of $S$, which can lead to a relatively small quartic coupling of $S$ with the SM-like Higgs and result in a sizable relic density. As a result the tension between the DM relic density and direct detection which occurs for the SM plus singlet case [20, 21] can be highly loosed in this scenario.
For the thermal history of the universe, the presence of the two additional scalars allows a two step EWPT. This happens as follows: As the universe cools down, $S$ gets vacuum expectation value (VEV) first and the universe transits to this phase; As the temperature gets lower, a second minimum occurs in the SM-like Higgs and $\Phi$ subspace. The universe then tunnels to this electroweak minimum resulting in a strongly first order EWPT with gravitational waves (GW) generated. GW signals coming from this two-step EWPT are calculated using one benchmark point of the parameter space and our results show that the corresponding GW signals are testable in the Evolved Laser Interferometer Space Antenna (eLISA), DECi-hertz Interferometer Gravitational wave Observatory (DECIGO), Ultimate-DECIGO and Big Bang Observer (BBO).

The remaining of this paper is organized as follows. Conventions of the model are defined in section 2. We then study the DM phenomenology in section 3 and the capability of a strongly first order EWPT in section 4. The GW calculations and discovery prospects are explored in section 5, after which we present a brief summary in section 6.

2 The model

We present the model for two-step phase transition and scalar DM in this section. The model extends the SM with two real scalar singlets: $S$ and $\Phi$, where $S$ is the DM candidate, while $\Phi$ gets non-zero VEV at the zero temperature and thus mixes with the SM Higgs.\(^1\) The Higgs potential can be written as

$$V_0 = -\frac{1}{2}\mu^2 \Phi^2 + \frac{1}{4}\lambda \Phi^4 - \frac{1}{2}\mu^2 S^2 + \frac{1}{4}\lambda S^4 - \mu^2 H^\dagger H + \lambda \left(H^\dagger H\right)^2 + \lambda_1 S^2 H^\dagger H + \lambda_2 \Phi^2 H^\dagger H + \lambda_3 S^2 \Phi^2,$$

(2.1)

where $H$ is the SM Higgs doublet. The effective potential, critical for the EWPT, can be written as: $V_{\text{eff}} = V_0 + V_{\text{CW}} + V_T$, where $V_0$ is the tree-level potential, $V_{\text{CW}}$ is known as the Coleman-Weinberg term [22], $V_T$ includes finite temperature contributions from loops [23] and bosonic ring [24, 25]. For one-step phase transition, where Higgs potential contains no tree-level cubic term, the barrier between the electroweak symmetric and broken phases usually arises from loop corrections and according to the Nielsen identity [26], the resulting effective potential is gauge dependent. For the two step phase transition, the barrier arises at the tree-level. So we include in the effective potential the standard one-loop $T \neq 0$ corrections, but only retain terms proportional to $O(T^2)$ for the consideration of gauge invariance. Thermal masses of scalars take the following forms:

$$\Pi_h = \left\{ \frac{3g^2 + g'^2}{16} + \frac{\lambda}{2} + \frac{b_4}{4} + \frac{\lambda_1 + \lambda_2}{12} \right\} T^2,$$

(2.2)

$$\Pi_s = \left\{ \frac{\lambda S}{4} + \frac{\lambda_1}{3} + \frac{\lambda_3}{6} \right\} T^2,$$

(2.3)

$$\Pi_\phi = \left\{ \frac{\lambda \Phi}{4} + \frac{\lambda_2}{3} + \frac{\lambda_3}{6} \right\} T^2.$$

(2.4)

\(^1\)Our particle settings are similar to these in ref. [11] where color breaking from two-step phase transition was proposed.
We require $S$ to have zero VEV at $T = 0$ for the stability of the DM and parametrize the other two fields by $H = (v_{EW} + h)/\sqrt{2}$ and $\Phi = \phi + \varphi$ with here $v_{EW} \approx 246$ GeV and $h_t \approx 1$. Minimization conditions around $(v_{EW}, v, 0)$ in the $(h, \phi, s)$ space allow us to trade the two VEVs $v_{EW}$ and $v$ for $\mu^2$ and $\mu^2_\phi$ by

$$\mu^2 = \lambda h v_{EW}^2 + \lambda_2 v_\phi^2, \quad \mu^2_\phi = \lambda_2 v_{EW}^2 + \lambda \phi v_\phi^2. \quad (2.5)$$

We also replace $\mu^2_S$ by the physical DM mass $m^2_S$,

$$\mu^2_S = \lambda_1 v_{EW}^2 + 2\lambda_3 v_\phi^2 - m^2_S. \quad (2.6)$$

With these substitutions, the mass matrix for $(h, \phi)$ is then given by

$$M^2 = 2 \left( \begin{array}{cc} v_{EW}^2 \lambda & v_{EW} v_\phi \lambda_2 \\ v_{EW} v_\phi \lambda_2 & v_\phi^2 \lambda \phi \end{array} \right), \quad (2.7)$$

which can be diagonalized by a $2 \times 2$ orthogonal matrix parametrized by a rotation angle $\theta$. The mass eigenstate $(\hat{h}, \hat{\phi})$ can then be written as

$$\hat{h} = c_\theta h + s_\theta \phi, \quad \hat{\phi} = -s_\theta h + c_\theta \phi. \quad (2.8)$$

where $c_\theta = \cos \theta$ and $s_\theta = \sin \theta$. We define $\hat{h}$ as the SM-like Higgs boson and therefore when $\theta \to 0$, $\hat{h}$ is purely the SM Higgs. With this definition, three of the parameters in the potential $\lambda, \lambda_2, \lambda_\phi$ can be replaced by the physical masses $m^2_h, m^2_\phi$ and $\theta$:

$$\lambda = \frac{m^2_h c^2_\theta + m^2_\phi s^2_\theta}{2v_{EW}^2}, \quad (2.9)$$

$$\lambda_2 = \sin(2\theta) \frac{m^2_h - m^2_\phi}{4v_{EW} v_\phi}, \quad (2.10)$$

$$\lambda_\phi = \frac{m^2_h s^2_\theta + m^2_\phi c^2_\theta}{2v_\phi^2}. \quad (2.11)$$

In summary, we have a total of 7 free parameters:

$$v_\phi, \quad m_\phi, \quad m_S, \quad \lambda_S, \quad \theta, \quad \lambda_1, \quad \lambda_3, \quad (2.12)$$

where $\lambda_1$ and $\lambda_3$ are relevant for the DM phenomenology.

Before proceeding to study EWPT and DM phenomenology, we discuss constraints on the mixing angle $\theta$ from Higgs measurements and electroweak precision measurements. Couplings of the SM-like Higgs to all SM particles are rescaled by the factor $c_\theta$ due to the mixing. As a result, signal rates, the ratio of Higgs measurements relative to the SM-like Higgs measurements, equal to $c^2_\theta$. Performing a universal Higgs fit to the data given by the ALTAS and CMS collaborations, one has $|\theta| \leq 0.526$ at the 95% CL [27]. It was shown in ref. [28] that the constraint of electroweak precision is closely related to the mass of $\hat{\phi}$, which is weaker than that of Higgs measurements for a light $\hat{\phi}$ and turns to be much strong as $m_\phi$ gets heavier. For constraints of vacuum stability and perturbativity, we refer the reader to refs. [29, 30] for detail.

For $m_\phi < 114$ GeV, the value of $\theta$ is constrained by the null result of the SM Higgs search at LEP, which was studied in ref. [28]. The limits are mass dependent and our selected benchmarks in the next two sections satisfy these constraints.
3 Dark matter

The fact that about 26.8% of the universe is made of DM, whose relic abundance is about $\Omega_c h^2 = 0.1189$ [31], has been well established, while the nature of the DM is still unknown. The Higgs potential in eq. (2.1), has $Z_2 \times Z_2$ discrete symmetry for $S$ and $\Phi$ respectively. At the zero temperature, $\Phi$ gets non-zero VEV and thus its corresponding $Z_2$ is broken. On the other hand, we require that the global minimum at $T = 0$ forbids a nonzero VEV in the $s$ direction. As a result $s$ can serve as a DM candidate, which interacts with the SM particles via the Higgs portal interactions. The couplings between the DM and the physical scalars are

$$s^2 \hat{h} = 2\lambda_3 v_\phi s_\theta + \lambda_1 v_{EW} c_\theta,$$  
(3.1)

$$s^2 \hat{\phi} = 2\lambda_3 v_\phi c_\theta - \lambda_1 v_{EW} s_\theta,$$  
(3.2)

$$s^2 \hat{h}^2 = \frac{1}{2} \lambda_1 c_\theta^2 + \lambda_3 s_\theta^2,$$  
(3.3)

$$s^2 \hat{\phi}^2 = \frac{1}{2} \lambda_1 s_\theta^2 + \lambda_3 c_\theta^2,$$  
(3.4)

$$s^2 \hat{h} \hat{\phi} = \cos \theta s_\theta (2\lambda_3 - \lambda_1).$$  
(3.5)

The relic density of the DM is governed by the Boltzmann equation:

$$\dot{n} + 3Hn = -\langle \sigma v \rangle (n^2 - n_{EQ}^2),$$  
(3.6)

where $H$ is the Hubble constant, $\langle \sigma v \rangle$ is the thermal average of the reduced annihilation cross section. For our model, the DM can annihilate into $\bar{f}f$, $ZZ/WW$, $\hat{h}\hat{h}$, $\hat{\phi}\hat{\phi}$ and $\hat{h}\hat{\phi}$ final states via $s$-channel Higgs mediations, where di-scalar processes also receive contribution from four point interactions in eq. (3.5). Compared with the most simple Higgs portal, here there are more annihilation channels for a heavy DM. Couplings in eqs. (3.1) and (3.2) are both relevant to the DM direct detections, while the contribution of $\hat{\phi}$ mediated processes is suppressed by the factor $s_\theta^2$ and thus is negligible for a small $\theta$. For numerical simulations we implement the model in LanHEP [32, 33] and use MicrOMEGAs [34, 35] to calculate the relic density.

For direct detections, the spin independent scattering cross section off nucleon is given by

$$\sigma_n = \frac{\mu^2 m_n^2}{\pi v_{EW} m_S^2} \left| \frac{c_\theta a_h}{m_h^2} - \frac{s_\theta a_\phi}{m_\phi^2} \right|^2 \left( \frac{2}{9} + \frac{7}{9} \sum_{q=u,d,s} f_{1q}^n \right)^2,$$  
(3.7)

where $a_h$, $a_\phi$ are effective couplings in eqs. (3.1) and (3.2) respectively and $f_{1q}^n$ are nucleon form factors for light quarks [36]. The inclusion of $\Phi$ that mixes with the SM Higgs can lead to a complete cancellation in contributions to $\sigma_n$ at tree level. This occurs when the effective coupling of DM with quarks vanishes, that is, when the expression in $|\cdots|$ vanishes.

Imposing this condition would allow us to eliminate one more parameter $\lambda_3$,

$$\lambda_3 = \frac{v_{EW} \lambda_1 (m_h^2 \tan \theta + m_\phi^2 \cot \theta)}{2v_\phi (m_h^2 - m_\phi^2)},$$  
(3.8)

which will be adopted in the following numerical analysis for simplicity. Actually $\lambda_3$ does not have to obey the eq. (3.8), one can decompose $\lambda_3$ as $\lambda_3^0 + \delta \lambda$, where $\lambda_3^0$ is the solution of the
eq. (3.8), then the direct detection cross section is proportional to $(\varepsilon_\theta \delta \theta \delta \lambda)^2$, which is severely constrained by the exclusion limits given by LUX [17], PandaX [18] and Xenon1T [19]. By setting $v_{\Phi} = 65 \text{ GeV}$, $m_{\hat{\varphi}} = 82 \text{ GeV}$, $m_S = 71 \text{ GeV}$, $\lambda_S = 0.015$, $\theta = 0.12$, $\lambda_1 = 0.046$ and $\lambda_3 = 0.57$, which is the benchmark of figure 4, one has $\delta \lambda/\lambda_3 < 5\%$, so the value of $\lambda_3$ provided by the Eq. (3.8) is a good approximation.

For a detailed survey of the parameter space, we perform a parameter scan and show the results in figure 1 in the plane $(m_S, \lambda_1)$ (left panel) and in the plane $(\theta, \lambda_1)$ (right panel). In these plots, the green points give the relic density within the range $\Omega h^2 \in (0.02, 0.12)$ allowed by the current results from Planck [31], in addition to being able to induce the desired pattern of two-step EWPT pattern as discussed later. From the plot in the left panel, we can see the coupling $\lambda_1$ that can give a relic density within this range is of magnitude $(0.005, 0.02)$ for a relatively heavy DM, while it can be larger $\approx 0.08$ for a relatively light DM. For the plot in the right-handed panel, the mixing angle $\theta$ can take positive or negative values depending on whether $m_{\hat{\varphi}}$ is smaller or larger than $m_{\hat{h}}$ to keep $\lambda_2$ positive, according to eq. (2.10). In both plots, the red points also satisfy the condition for the strongly first order EWPT $v_h(T_n)/T_n \gtrsim 1$, where $T_n$ is the nucleation temperature to be defined later. It shows that a big proportion of the green points do not satisfy this condition, mostly due to the incapability to meet the condition of bubble nucleation. It is also clear from the right-panel plot that mostly those with positive $\theta$ can satisfy this condition, which corresponds to requiring $\hat{\varphi}$ to be lighter than $\hat{h}$. For the green points in these two figures, we further show the distribution of the value of $\lambda_3$ in the left panel figure 2 which is calculated using eq. (3.8) to nullify the direct detection signal. Here most of the points have $\lambda_3 \lesssim 0.7$ and this distribution shows a peak at $\lambda_3 \approx 0.1$. To assess the validity of eq. (3.8), we calculate the maximum value of $\delta \lambda$ that gives a direct detection cross section falling below the LUX exclusion limit for each scanned point shown in the figure 1 and show the distribution of $\delta \lambda/\lambda_3$ in the right panel.
Figure 2. The distribution of $\lambda_3$ (left panel) and $\delta\lambda/\lambda_3$ (right panel) for the green points in figure 1. So every point used here nullifies the direct detection cross section by choosing $\lambda_3$ as a function of the other parameters according to eq. (3.8), gives the DM relic density $\Omega_c h^2 \in (0.02, 0.12)$ and generates the desired two-step EWPT.

of figure 2. We observe that $\delta\lambda$ is less than 0.1 for all points, and about 65% of these green points as well as all red points satisfy $\delta\lambda/\lambda_3 < 10\%$. For each of above shown point, the $\lambda_3$ given by eq. (3.8) serves as a representative of all the values of $\lambda_3$ which are compatible with the direct detection constraint, as our main purpose of this paper is studying the EWPT and the resulting GWs. The above distributions in figure 2 then show that this simplified treatment here can reflect a more practical and extensive study of the parameter space.

4 Electroweak phase transition

The barrier between the electroweak symmetric and broken phases emerges at the tree-level in our two-step phase transition scenario. As a result, the effective potential, which includes the standard one-loop $T \neq 0$ corrections but only retain the leading terms (thermal mass terms) in the high $T$ expansion so as to avoid problems relating to the gauge dependence, can be written as

$$V_{\text{eff}} = -\frac{1}{2} (\mu_\Phi^2 - \Pi_\phi) \phi^2 - \frac{1}{2} (\mu_S^2 - \Pi_s) s^2$$

$$- \frac{1}{2} (\mu^2 - \Pi_h) h^2 + \frac{1}{4} \lambda h^4 + \frac{1}{2} \lambda_1 s^2 h^2 + \frac{1}{2} \lambda_2 \phi^2 h^2$$

$$+ \lambda_3 s^2 \phi^2 + \frac{1}{4} \lambda_\phi \phi^4 + \frac{1}{4} \lambda_s s^4,$$  \hspace{1cm} (4.1)

in terms of background fields $h$, $\phi$ and $s$.

Given eq. (4.1), one can trace the evolution of the universe phase as temperature drops and our desired pattern of EWPT is illustrated in figure 3. At sufficiently high temperature, the universe sits at the global minimum $(0, 0, 0)$ where the electroweak symmetry is restored. As temperature drops to $T_s$, a minimum develops in the $s$ direction and due to an absence of a barrier with the one at the origin, the universe transits to this minimum through a second order phase transition. As $T$ continues decreasing to $T_h$, a second minimum develops in the
Figure 3. This figure gives an illustrative picture of the two step EWPT with the first step in the \(s\) direction and the subsequent one from \(s\) direction to the \((h, \phi)\) direction.

\((h, \phi)\) direction but its free energy is initially higher than the one in the \(s\) direction. As \(T\) further decreases, the free energy of the minimum in the \((h, \phi)\) direction drops faster than the one in the \(s\) direction, and at the critical temperature \(T_C\), these two minima become degenerate. Slightly below \(T_C\), the universe makes a second transition to the global minimum in the \((h, \phi)\) direction. Due to the existence of the barrier between these two minima, the transition may occur as a first order EWPT by a tunneling process and proceeds through nucleations of electroweak bubbles [37–39] which expand, collide and coalesce, leaving eventually the universe in the electroweak broken phase. We assume that the BAU is generated by the electroweak baryogenesis mechanism, which generates the baryon asymmetry during the first order EWPT. To avoid washing out of the generated baryons by the sphaleron process inside the electroweak bubble, the sphaleron process needs to be sufficiently suppressed inside the bubble and this translates into the following generally adopted criterion [2, 3, 40]:

\[
\frac{v_h(T_n)}{T_n} \gtrsim 1, \quad (4.2)
\]

where \(T_n\) is the bubble nucleation temperature. This is a more precise characterization of the sphaleron washing-out criterion than the condition evaluated at the critical temperature \(T_C\) \((v_h(T_C)/T_C \gtrsim 1)\), since \(T_n\) turns out not so close to \(T_C\) in many cases. Note also that due to the reflection symmetry of the effective potential under \(h \rightarrow -h, \phi \rightarrow -\phi\) or \(s \rightarrow -s\), there are identical phase structures and we focus on the region with \(h, \phi, s > 0\).

The VEV of the SM Higgs at the finite temperature can be written as

\[
v_h(T) = \sqrt{v_{EW}^2 + \frac{\lambda_2 \Pi_{\phi} - \lambda_\phi \Pi_h}{\lambda \lambda_\phi - \lambda_\phi^2}}. \quad (4.3)
\]

The critical temperature \(T_C\) can be calculated analytically from the following equation:

\[
\lambda \left(\mu_\phi^2 - \Pi_\phi\right)^2 - 2\lambda_2 \left(\mu^2 - \Pi_h\right) \left(\mu_\phi^2 - \Pi_\phi\right) + \lambda_\phi \left(\mu^2 - \Pi_h\right)^2 = \left(\mu_\phi^2 - \Pi_\phi\right)^2, \quad (4.4)
\]

where \(\mu^2, \mu_\phi^2\) and \(\mu_S^2\) can be written in terms of physical parameters.
As a concrete example, we show in the left panel of figure 4, the evolution of $V$ at these two minima as the temperature drops from right to the left, for the parameter choice $v_\phi = 65 \text{ GeV}$, $m_\phi = 82 \text{ GeV}$, $m_S = 71 \text{ GeV}$, $\lambda_S = 0.015$, $\theta = 0.12$, $\lambda_1 = 0.046$ and $\lambda_3 = 0.57$ which gives $v_b(T_n)/T_n = 5.6$. Here the horizontal green line on the far right denotes the symmetric phase at high temperature when the universe sits at the origin, the magenta dashed line represents the minimum in the $s$ direction and the blue line is the minimum in the $(h, \phi)$ direction which eventually evolves to the electroweak minimum at the zero temperature labeled by a red dot. The $s$ direction phase appears at $T_s = 150 \text{ GeV}$ continuously away from the origin while the $(h, \phi)$ direction phase starts from $(159 \text{ GeV}, 9.15 \text{ GeV}, 0)$ at $T_h = 108 \text{ GeV}$ above which it is a saddle point. The $T$ at which the blue and magenta lines intersect is the critical temperature $T_C = 78.8 \text{ GeV}$ and is labeled by a black dot. At $T_C$, the two minima are $(205 \text{ GeV}, 45 \text{ GeV}, 0)$ and $(0, 0, 352 \text{ GeV})$. For more details on the evolution of the minimum in the $(h, \phi)$ direction, we plot in the right panel the track of this minimum in blue dotted line for the whole thermal history with here the red arrow denoting the direction as temperature drops. The contours in this plot gives an measure of the value $V$ at $T = 0$ and the electroweak vacuum labelled by the red point sits at the deepest location. For this parameter choice we have $v_b(T_n)/T_n = 5.6$ and thus the strongly first order EWPT criterion eq. (4.2) is achieved.

A more comprehensive survey of the model is given by a scan over the parameter space as shown in figure 1 where all plotted points give above described pattern of EWPT by imposing various conditions during the scan. These conditions include: (i) there are two minima in the field space with one in the $s$ direction and the other in $(h, \phi)$ direction; (ii) the electroweak minimum needs to be lower than the one in the $s$ direction at $T = 0$ should the $s$ direction minimum persist at $T = 0$; (iii) the minimum in the $s$ direction occurs earlier than the one in the $(h, \phi)$ direction, that is, $T_s > T_h$. After imposing these conditions, the points are further filtered to give a relic density in the range $(0.02, 0.12)$ with the remaining
plotted using green color. At this step, these points can give a two-step EWPT and a sizable amount of relic density but the second step EWPT is not necessarily strongly first order. As such, we further calculate the critical temperature $T_C$ and $v_h(T_C)$ corresponding to the black intersection point of the blue and magenta lines for each above green point. The points which satisfy the condition in eq. (4.2) are shown with red color in figure 1. So we can see there are sufficient parameter space in this model where the desired strongly first order EWPT pattern can be realized. We note in passing that the second order phase transition for the first step could also be strongly first order, should a more complete effective potential be adopted.

5 Gravitational waves

The calculation of the GWs generated during the second step EWPT needs a numerical analysis of the tunneling process at finite temperature and in particular involves solving the critical bubble profiles. As mentioned in previous section, after the universe cools down to a temperature below $T_C$, the second transition from $(0, 0, v_s)$ to the true vacuum $(v_h, v_{\phi}, 0)$ takes place by the nucleation of true vacuum bubbles. This tunneling rate per unit time per unit volume reads [41]

$$\Gamma \sim A(T) e^{-S_3/T},$$

(5.1)

where $S_3$ is the Euclidean action of the critical bubble which minimizes the action

$$S_3(\phi, T) = 4\pi \int r^2 dr \left[ \frac{1}{2} \left( \frac{d\phi(r)}{dr} \right)^2 + V(\phi, T) \right],$$

(5.2)

and the prefactor $A(T)$ is roughly $O(T^4)$, whose precise evaluation needs integrating out fluctuations around the bounce solution [42]. From this rate formula, the bubble nucleation temperature $T_n$ is defined as the probability for a single bubble to be nucleated within one horizon volume being $O(1)$, i.e.

$$\int_0^{T_n} \Gamma V_H(t) dt = \int_{T_n}^{\infty} \frac{dT}{T} \left( \frac{2\zeta M_{pl}}{T} \right)^4 e^{-S_3/T} = O(1),$$

(5.3)

where $V_H(t)$ is the horizon volume, $M_{pl}$ is the Planck mass and $\zeta \sim 3 \times 10^{-2}$. This equation implies numerically $S_3(T_n)/T_n \approx 140$ [43] and serves as our definition of $T_n$. From the bounce solutions, two other important parameters $\alpha$ and $\beta$, that are directly relevant for the calculation of GWs, are defined by:

$$\alpha \equiv \frac{\rho_{vac}}{\rho_{rad}}, \quad \beta \equiv H_n T_n \frac{d(S_3/T)}{dT} \bigg|_{T_n},$$

(5.4)

where $\rho_{vac}$ is the vacuum energy density released in the phase transition, $H_n$ is the Hubble parameter at $T_n$, $\rho_{rad}^* = g_s \pi^2 T_n^4/30$ with $g_s$ the relativistic degrees of freedom in the plasma at $T_n$. A small $\beta/H_n$ will trigger strong phase transition and consequently a significant stochastic background of GWs.

The observable characterizing the GW background is the energy spectrum $h^2 \Omega_{GW}(f)$ and is given by [43]

$$h^2 \Omega_{GW}(f) = \frac{h^2}{\rho_c} \frac{d\rho_{gw}}{d \log f},$$

(5.5)

where $\rho_{gw}$ is the energy density of GWs with $f$ its frequency and $\rho_c$ is the critical energy density today. The sources of stochastic GW signals arising from first order EWPT can
be classified into three categories: (1) collisions of bubble walls and shocks in the plasma; (2) sound waves in the plasma after the bubble collision; (3) Magnetohydrodynamic (MHD) turbulence in the plasma [44]. The total energy spectrum is given approximately by the sum of these three sources,

$$h^2 \Omega_{\text{GW}} \approx h^2 \Omega_{\text{coll}} + h^2 \Omega_{\text{sw}} + h^2 \Omega_{\text{turb}}.$$

The GW contribution from bubble collisions can be calculated using the envelope approximation [45–47], which numerically results in the following GW contribution to the spectrum [48]:

$$h^2 \Omega_{\text{coll}}(f) = 1.67 \times 10^{-5} \left( \frac{H_n}{\beta} \right)^2 \left( \frac{\kappa \alpha}{1 + \alpha} \right)^2 \left( \frac{100}{g_*} \right)^{1/3} \times \left( \frac{0.11 v_w^3}{0.42 + v_w^2} \right) \left[ \frac{3.8(f/f_{\text{coll}})^{2.8}}{1 + 2.8(f/f_{\text{coll}})^{3.8}} \right],$$

where $v_w$ is bubble wall velocity, $\kappa$ characterizes the fraction of latent heat deposited in a thin shell and $f_{\text{coll}}$ is the peak frequency produced by the bubble collisions. At the time of the phase transition $f_{\text{coll}}^n = 0.62 \beta/(1.8 - 0.1 v_w + v_w^2)$, which is red-shifted to give the peak frequency today: $f_{\text{coll}} = f_{\text{coll}}^n \times a(T_n)/a_0 = 16.5 \times 10^{-6}$ Hz $(f_{\text{coll}}^n/H_n)(T_n/100 \text{ GeV}) \times (g_*/100)^{1/6}$. Both $v_w$ and $\kappa$ are functions of $\alpha$, which read as [49]:

$$v_w = \frac{1/\sqrt{3} + \sqrt{\alpha^2 + 2\alpha/3}}{1 + \alpha}, \quad \kappa \approx \frac{0.7 \alpha + 0.2 \sqrt{\alpha}}{1 + 0.7 \alpha}.$$ (5.8)

The sound wave contribution of the GW intensity is numerically fitted by

$$h^2 \Omega_{\text{sw}}(f) = 2.65 \times 10^{-6} \left( \frac{H_n}{\beta} \right) \left( \frac{\kappa_w \alpha}{1 + \alpha} \right)^2 \left( \frac{100}{g_*} \right)^{1/3} \times v_w \left( \frac{f}{f_{\text{sw}}} \right)^3 \left[ \frac{7}{4 + 3(f/f_{\text{sw}})^2} \right]^{7/2},$$

where $\kappa_w$ denotes the fraction of latent heat transformed into bulk motion of the fluid, $f_{\text{sw}}$ is the peak frequency that can be given from the rescaling of its value at the phase transition, i.e. $f_{\text{sw}} = f_{\text{sw}}^n \times a(T_n)/a_0 = (2/\sqrt{3})(\beta/v_w) \times a(T_n)/a_0$. We refer the reader to refs. [44, 50] for the value of $\kappa_w$ in the small and large $v_w$ limit. The MHD turbulence contribution to the GW spectrum can be written as

$$h^2 \Omega_{\text{turb}}(f) = 3.35 \times 10^{-4} \left( \frac{H_n}{\beta} \right) \left( \frac{\kappa_{\text{tu}} \alpha}{1 + \alpha} \right)^{3/2} \left( \frac{100}{g_*} \right)^{1/3} \times v_w \left( \frac{f}{f_{\text{tu}}} \right)^3 \left( 1 + f/f_{\text{tu}} \right)^{11/3} \left( 1 + 8 \pi f/h_n \right),$$

where $\kappa_{\text{tu}} \approx 0.1 \kappa_w$ [51], $h_n$ is the Hubble parameter today, and $f_{\text{tu}} \approx (3.5/2)(\beta/v_w) \times a(T_n)/a_0$.

We use the package CosmoTransitions [52] to solve for profiles of the critical bubble and the nucleation temperature for the benchmark point used earlier. This parameter choice gives $\Omega_c h^2 = 0.04$ constituting about 34% of the total DM relic density. For this benchmark parameter point, we show in the left panel of figure 5 the quantity $S(T)/T$ as a function of $T$ and we found $T_n = 41.2 \text{ GeV}$. The resulting GW signals are shown in the right panel of
Figure 5. The left panel shows changes of $S(T)/T$ in the neighborhood of $T_n$ and the right panel shows the GWs generated during the first order EWPT as a function of frequency from three sources: sound waves (blue dot-dashed line), collision (red dotted line), turbulence (green dashed line) and total contribution (cyan solid line). The color shaded regions fall within the experimental sensitivities of eLISA (four configurations with notation NiAjMkLl), ALIA (gray), BBO (green), DECIGO (yellow) and Ultimate-DECIGO (purple).

figure 5 where the three contributions are shown with details in the caption. As can be seen from this figure, the blue sound wave contribution dominates and is almost indistinguishable from the sum of the three sources which is denoted by the cyan line. For a comparison with experiment, we show firstly four sensitive regions corresponding to four configurations of the eLISA detector. These four regions are labelled in the format NiAjMkLl and are plotted as the red shaded regions at the top following conventions of refs. [44, 53]. We can see for this parameter set, the GWs can be detected by the configuration N2A5M5L6 while unreachable by the others. We further add the sensitive regions of several other proposed decihertz GW experiments: Advanced Laser Interferometer Antenna (ALIA) [54], BBO, DECIGO and Ultimate-DECIGO [55]. The data are taken from refs. [56–58] and are plotted as gray, green, yellow and purple regions respectively. From the plot, we can see the GW signals from the benchmark point fall within the detectable ranges of BBO, DECIGO and Ultimate-DECIGO. It should be noted that there might be other points in the model parameter space where the generated GWs can have much larger energy density spectrum and are therefore within reach of the other three eLISA configurations as well as ALIA, and give a sufficiently large DM relic density in the meanwhile. This however needs a dedicated survey of the parameter space including all the considerations and we leave it to future works. For GWs from one-step EWPT in SM extended with scalar singlet(s), we refer the reader to refs. [62–68] as well as references cited in these papers for detail. Alternatively, first order phase transition may lead to origina-
tions of primordial black holes. They can be captured by neutron stars or astrophysical black holes [69], resulting in GWs that may be detected by Advanced LIGO or Advanced Virgo.

6 Summary

Working in a simple model with the SM extended by a scalar singlet DM and another scalar singlet which mixes with the SM-like Higgs boson, we studied a possible connection between the DM phenomenology and the EWPT, in particular the detectability of the GW signals generated during the DM assisted EWPT. Through both analytical and numerical studies, we find this model may admit strongly first order two-step EWPT in certain parameter space, which may also give rise to a viable DM relic density and a negligible direct detection cross section. We further exemplified, using one representative benchmark point, the discovery possibility of the EWPT with the generated GW signals during the second step EWPT and found that the GW signals can be detected by the eLISA in the configuration N2A5M5L6, BBO, DECIGO and Ultimate-DECIGO. This scenario can readily be generalized to other models where DM can have nontrivial effect in the baryon number generation and is helpful in understanding and testing the origin of these two cosmological puzzles.
