Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Ubiquitous convalescent plasma: An artificial universal plasma for COVID-19 patients

Antibody titer

ABSTRACT

Objectives and background: In December 2019, the first case of COVID-19 was reported in Wuhan, China. Its causative virus, a novel strain of RNA viruses with high mortality rate. There is no definitive treatment, but among available approaches the use of recovered patients’ plasma containing specific antibodies can enhance the immune response against coronavirus. However, the dearth of eligible donors and also ABO incompatibility in plasma transfusion, have limited this therapeutic method. Therefore, it is highly desirable to introduce a simple procedure that allows efficient reduction or even removal of natural ABO antibodies. Accordingly, we aimed to evaluate a RBC-mediated adsorption technique that reduces the titer of the mentioned antibodies in plasma.

Methods/materials: This experimental study was conducted in Kerman University of Medical Sciences, Kerman, Iran. The pre- and post-incubation antibody titers of 168 plasma samples were determined. For incubation, each plasma sample was exposed (60 min) to different percentages of RBCs at room temperature or 4 °C.

Results: The results evidenced that both the concentration of RBCs and temperature had significant decreasing effects on antibody titer (P < 0.001) and all concentrations significantly reduced titer. Compared to RT, 4 °C further reduced the antibody titer. Overall, the best incubation condition for reducing antibody titer in all blood groups was 4 °C and 2% RBCs concentration.

Conclusion: The presented adsorption procedure is able to produce universal plasma (we call it Ubiquitous Convalescent Plasma) with a non-immunogenic level of ABO mismatch antibodies which can be used for COVID-19 patients with any type of blood group with desirable simplicity, feasibility, and efficacy.

1. Introduction

Coronavirus disease 2019 (COVID-19), which is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was first identified in late December 2019 in Wuhan, China and rapidly spread worldwide [1,2]. Until December 2020, the COVID-19 pandemic infected 82 million people and caused nearly 1.79 million deaths [3]. The exponentially increasing rate of cases infected with COVID-19 has prompted researchers to seek effective and definitive therapeutic options. Besides pharmacotherapy [4,5], other remedies such as convalescent plasma (CP) therapy, vaccination, and stem cell therapy are under investigation in several clinical trials [1,6]. Nowadays, CP therapy is considered a safe, effective, and FDA-approved immunotherapy approach [7] which is utilized for different diseases such as SARS, Middle East respiratory syndrome coronavirus, Ebola, Zika, and pandemic influenza A [1,8,9]. In this therapeutic option, recovered patients’ plasma containing pathogen-specific antibodies are used to provide immediate immunity [1,5,8]. Although this approach can be
effective in the COVID-19 patients [10], it has some limitations including the dearth of eligible recovered patients and ABO-incompatibility. Except for individuals with AB blood group (universal plasma donors) [11], others have cold reactive natural antibodies directed against red blood cells (RBCs), high concentration (>1:64) of which leads to various complications and symptoms [12]. Despite the mentioned practical advantage of the AB group, low prevalence limits its widespread application for CP therapy; the frequency of blood groups is race/ethnicity-dependent, but overall, their prevalence in white populations is as follows: O > A-B > AB (45%, 40%, 11%, and 4%, respectively) [13]. Therefore, it is critical to find methods that allow transfusion of ABO-mismatched plasma. Accordingly, for the first time, we decided to optimize an adsorption method to produce a universal plasma that can be transfused into patients with any blood group. By obviating the deficiency of matched donors, this process allows the widespread use of CP therapy in the treatment of various diseases such as COVID-19.

2. Materials and methods

2.1. Blood collection

The current study was approved by the ethical review committee affiliated with Kerman University of Medical Sciences, Kerman, Iran. Before blood collection, informed consent was obtained from 168 healthy donors (56 samples from each A, B, and O blood group; 7 samples for each incubation condition). In a sterile condition, whole blood was collected into bags containing an FDA-approved anticoagulant preservative solution (Citrate-Phosphate-Dextrose-Adenine). The ABO group, Rh type, and anti-viral antibodies (anti-hepatitis C virus and anti-human immunodeficiency virus 1/2 antibodies) were determined for each donor. Using differential centrifugation, plasma was separated from whole blood and platelets, then stored at −20 °C.

2.1.1. Antibody titration

Based on the type of plasma and packed cells, for initial titration, the samples were divided into four groups: 1) Plasma A tittered with B packed cells (A–B), 2) Plasma B tittered with A packed cells (B–A), 3) Plasma O tittered with A packed cells (O–A), and 4) Plasma O tittered with B packed cells (O–B). Next, antibody titration was performed as follows: Ten test tubes were assigned for serial dilution and 500 μL of saline was transferred to tubes 2–10. After the addition of 500 μL plasma to tubes 1 and 2, tube 2 was mixed thoroughly and 500 μL of its content was transferred into the next tube. This process was repeated for the next tubes and eventually, 500 μL of contents of tube 10 was removed. Therefore, tubes 1–10 contained undiluted plasma and dilutions of 1/2, 1/4, 1/8, 1/16, 1/32, 1/64, 1/128, and 1/512 of plasma, respectively. Finally, 10 μL of related packed RBCs was transferred into each tube (final concentration = 2%) and after centrifugation (1000 ×g/30 s), agglutination was examined macroscopically. The last serum dilution with visible agglutination was defined as the antibody titer [14].

2.2. Adsorption procedure

According to the packed red cell concentrations (0.5, 1, 2, and 4%) and incubation temperature (room temperature (RT) and 4 °C), the samples were divided into 32 groups: 1) Plasma A incubated with B packed cells (0.5%) at RT, 2) Plasma A incubated with B packed cells (1%) at RT, 3) Plasma A incubated with B packed cells (2%) at RT, 4) Plasma A incubated with B packed cells (4%) at RT, 5) Plasma A incubated with B packed cells (0.5%) at 4 °C, 6) Plasma A incubated with B packed cells (1%) at 4 °C, 7) Plasma A incubated with B packed cells (2%) at 4 °C, 8) Plasma A incubated with B packed cells (4%) at 4 °C, and as the same way, 8 groups for plasma B (incubated with A packed cells), 8 groups for plasma O (incubated with A packed cells), and 8 groups for plasma O (incubated with B packed cells). To perform adsorption procedure, in each group, 5 mL of plasma was mixed with 25, 50, 100, or 200 μL of related packed red cells (final concentrations of packed cells = 0.5, 1, 2, and 4%) and incubated for 60 min at RT or 4 °C. The mixture was shaken during the incubation phase periodically and then centrifuged at 1000 ×g for 5 min to form tightly-packed cells. Finally, the supernatant was harvested for the secondary antibody titration according to section 2.2. procedure.

2.3. Statistical analysis

Statistical analysis was performed using the IBM SPSS Statistics 23 software. Reciprocal antibody titers were transformed into log_{10} for prior to analysis [15,16]. The comparisons of antibody titer reduction in different temperatures and RBC concentrations were performed by two-way analysis of covariance (ANCOVA). The initial titer was used as the concomitant covariate in ANCOVA analysis for adjustment. The initial assumptions of ANCOVA analysis (normality and homogeneity of regression slopes) were also checked. The level of significance was considered P < 0.05. Results were presented as mean ± standard error (SE).

3. Results

Overall, the concentration of RBC and incubation temperature had significant decreasing effects on antibody titer (P < 0.001). However, the interaction between the concentration of RBCs and temperature was not statistically significant (A-B: P = 0.242, B-A: P = 0.891, O-A: P = 0.198, and O-B: P = 0.374). The Bonferroni pairwise comparison test between different concentrations of RBCs showed that all concentrations significantly reduced antibody titer (P < 0.05). Concerning temperature, this comparison test evidenced that 4 °C had a significantly higher decreasing effect on antibody titer compared to RT (A-B, O-A, and O-B: P < 0.001 and B-A: P < 0.01). Furthermore, incubation at 4 °C had a higher decreasing effect on antibody titer in all concentrations of RBCs. According to Fig. 1, the antibody titer alterations had a linear relationship with RBC concentrations. The lowest concentration of RBCs that declined the antibody titer to an acceptable level (<1:64) was 2 percent.

4. Discussion

There is no specific approved protocol for the treatment of COVID-19, but some antiviral drugs and adjunctive therapies (use of blood products and immunomodulators) can be applied for the alleviation of coronavirus inflammatory effects [17,18]. For instance, stem cells with immunomodulatory properties as well as CP can be added to the treatment protocols of COVID-19 [19]. Donated plasma from recovered patients has been investigated in the treatment of many infectious diseases such as H1N1 influenza, SARS, and Ebola [20]. This blood product is cost-effective and provides passive immunization by virus-specific antibodies, limits virus replication, and accelerates immune response to viral infection [21,22]. Recently, this modality has been noticed as promising supportive treatment for COVID-19 patients and its proper usage at an early stage of the disease can reduce hospitalization [23]. In this regard, Duan et al. treated 10 COVID-19 patients with 200 mL CP within 4 h (antibody titer:1:640); the results evidenced improvement of clinical symptoms, enhancement of oxyhemoglobin, increase/maintenance of the pathogen-neutralizing antibody titer, and lack of adverse effects [1]. Furthermore, in a clinical trial carried out by Chen and colleagues, transfusion of CP in 10 COVID-19 patients led to the improvement of respiratory problems, lymphocyte increase, and inflammation suppression [10]. Another case study by Shen et al. demonstrated that CP transfusion (400 mL, antibody titer:1:1000) in 5 patients with severe clinical symptoms increased the pao2/fio2 ratio and neutralizing antibody titer from 40–60 to 80–320 [2]. In addition,
available findings from other experiments revealed that CP therapy along with recommended drug protocols could be considered as a safe and effective method for disease improvement and mortality reduction [24,25]. However, ABO-matched donor availability from COVID-19-recovered patients is a challenging issue since incompatible plasma (we call it Ubiquitous Convalescent Plasma) with a non-immunogenic level of ABO mismatch antibodies which can be used for different infectious diseases such as COVID-19 patients with any type of blood group with desirable simplicity, feasibility, and efficacy.
