Abstract. We study the influence of hadron interaction features on the high-energy atmospheric neutrino spectrum. The 1D calculation is performed with use of the known high-energy hadronic models, SIBYLL 2.1, QGSJET-II, Kimel and Mokhov, for the parameterizations of primary cosmic ray spectra issued from the measurement data. The results are compared with the Frejus data and AMANDA-II measurements as well as with other calculations. Sizable difference of the neutrino fluxes (up to the factor of 1.8 at 1 TeV) that are obtained with the SIBYLL and QGSJET-II appears to be rather unexpected keeping in mind the hadron and muon flux calculations in the same energy region.

Keywords: atmospheric neutrinos, high-energy hadronic interactions

I. INTRODUCTION

Atmospheric neutrinos (AN) appear in decays of mesons (charged pions, kaons etc.) produced through collisions of high-energy cosmic rays with air nuclei. The AN flux in the wide energy range remains the issue of the great interest since the low energy AN flux is a research matter in the neutrino oscillations studies, and the high energy atmospheric neutrino flux is now appearing as the unavoidable background for astrophysical neutrino experiments [1], [2], [3], [4], [5], [6]. To present day a lot of calculations are made of atmospheric neutrino fluxes, among which [7], [8], [9], [10], [11], [12], [13], [14], [15] (see also [16], [17], [18], [19], [20] for a review of 1D and 3D calculations of the AN flux in the wide energy range).

In this work we present results of new one-dimensional calculation of the atmospheric muon neutrino flux in the range $10^3$–$10^7$ GeV made with use of the hadronic models QGSJET-II 03 [21], SIBYLL 2.1 [22] as well as Kimel and Mokhov (KM) [23] that were tested also in recent atmospheric muon flux calculations [24]. We make an attempt to learn how strongly the diversity of hadronic interaction models influences on the high-energy spectrum of atmospheric neutrinos.

II. THE METHOD AND INPUT DATA

The calculation is performed on the basis of the method [25] of solution of the hadronic cascade equations in the atmosphere, which takes into account non-scaling behavior of inclusive particle production cross-sections, the rise of total inelastic hadron-nuclei cross-sections, and the non-power law primary spectrum (see also [24]). As the primary cosmic ray spectra and composition in wide energy range used is the model recently proposed by Zatsepin and Sokolskaya (ZS) [26], which fits well the ATIC-2 experiment data [27] and supposedly to be valid up to 100 PeV. The ZS proton spectrum at $E \gtrsim 10^6$ GeV is compatible with KASCADE data [29] as well the helium one is within the range of the KASCADE spectrum recontructed with the help of QGSJET 01 and SIBYLL models. Alternatively in the energy range $10^6$–$10^7$ GeV we use the parameterization by Gaisser, Honda, Lipari and Stanev (GH) [18], [29], the version with the high fit to the helium data. Note this version is consistent with the data of the KASCADE experiment at $E_\nu > 10^6$ GeV that was obtained (through the EAS simulations) with the SIBYLL 2.1.

To illustrate the distinction of the hadron models employed in the computations, it is appropriate to compare the spectrum-weighted moments (Table I) computed for proton-air interactions (for $\gamma = 1.7$):

$$z_{pc}(E_\nu) = \frac{1}{\sigma_{pc}} \frac{d\sigma_{pc}}{dx} dx,$$

where $x = E_\nu/E_0$, $c = p, n, \pi^\pm, K^\pm$. The values in Table I display approximate scaling law both in SIBYLL 2.1 and KM and little violation of the scaling in the QGSJET-II for $p$ and $\pi^\pm$.

III. ATMOSPHERIC MUON NEUTRINO FLUXES

Along with major sources of the muon neutrinos, $\pi_{\mu 2}$ and $K_{\mu 2}$ decays, we consider three-particle semileptonic decays, $K_{\mu 3}$, $K_{\mu 3}^0$, the contribution originated from decay chains $K \rightarrow \pi \rightarrow \nu_\mu$ ($K_S^0 \rightarrow \pi^+ \pi^- \nu_\mu$, $K_L^0 \rightarrow \pi^\pm \nu_\mu$), as well as small fraction from the muon decays.

One can neglect the 3D effects in calculations of the atmospheric muon neutrino flux near vertical at energies $E \gtrsim 1$ GeV and at $E \gtrsim 5$ GeV in case of directions close to horizontal (see [19], [20]). Fractions of the neutrino flux near vertical from pion and kaon decays are shown in Fig. I. These calculations are made for the model primary spectrum by GH [18] (Fig. I) as well for the model by ZS [26] that comprises the results of ATIC-2 experiment [27] (Fig. II). Note the similar ratio for muon fluxes differs from that of neutrino fluxes: at $10^3$ GeV the $\mu_K/\mu_\pi$ ratio is about 0.25, while the $\nu_K/\nu_\pi$ is about 4 (see also Fig. I in Ref. [18]).
The ratio $\nu_\mu/\bar{\nu}_\mu$ calculated with KM model for the two primary spectra, GH and ZS, is plotted in Fig. 2. The wavy shape of the ratios apparently visible in Figs. 1b and 2 reflects the peculiarities of the ZS spectra.

A comparison of $(\nu_\mu + \bar{\nu}_\mu)$ flux calculations for the three hadronic models under study is made in Table II, column 1, 2 and 3 presents the flux ratio, $\phi_{\nu_\mu}(\text{SIBYLL})/\phi_{\nu_\mu}(\text{KM})$, $\phi_{\nu_\mu}(\text{QGSJET-II})/\phi_{\nu_\mu}(\text{KM})$ and $\phi_{\nu_\mu}(\text{SIBYLL})/\phi_{\nu_\mu}(\text{QGSJET-II})$ correspondingly, calculated at $\theta = 0^\circ$ and $90^\circ$ (in brackets) with usage of the GH and ZS primary spectra. One can see that usage of QGSJET-II and SIBYLL models leads to apparent difference of the muon neutrino flux, as well as in the case of SIBYLL as compared to KM (unlike the muon flux, where SIBYLL and KM lead to very similar results [24]). On the contrary, the QGSJET-II neutrino flux is very close to the KM one: up to 100 TeV the difference does not exceed 5% for the GH spectrum and 10% for the ZS one at $\theta = 0^\circ$. While the muon flux discrepancy in the QGSJET-II and KM predictions is about 30% at vertical [24]. The origin of differences is evident: the

| $10^{11}$    | 0.89 (0.75) | 0.48 (0.43) | 1.85 (1.74) |
FIGURE 3: Comparison of the two independent calculations for the GH spectrum.

Figure 3 shows this work calculations of the neutrino flux (lines) in comparison with the result of Barr, Gaisser, Lipari, Robbins and Stanev (BGLRS) [19] obtained with use of the TARGET 2.1 (symbols). All these computations are performed for the GH primary spectra. One can see the calculations for KM and TARGET 2.1 are in almost agreement in the range $10^{-4} - 10^{-1}$ GeV near horizontal as well as at $E_\nu < 200$ GeV near vertical.

In Fig. 4 presented is the comparison of different calculations of the AN flux along with the data of the AMANDA-II [3, 4] and Frejus [30] experiments. More comparisons of the low and high energy flux calculations may be found in Refs. [12, 13, 16, 17, 19].

Figure 5 presents the comparison of this work calculation of the conventional (from $\mu$, $\pi$, $K$-decays) and prompt muon neutrino flux with some of previous ones [13, 17, 31, 32, 33]. The conventional flux here was calculated with use of QGSJET-II model combined with the Zatsepin and Sokolskaya primary spectrum (thin lines). Dashed lines mark the calculation with Naumov, Sinegovskaya and Sinegovsky [13, 17] of the conventional muon neutrino fluxes for $\theta = 90^\circ$. Bold dotted line (curve 1) shows the sum of the prompt neutrino flux by Volkova and Zatsepin (VZ) [32] and the conventional one due-to the QGSJET-II + ZS model at $\theta = 90^\circ$. Dash-dotted line (2) marks the sum of the QGSJET-II conventional flux ($\theta = 90^\circ$) and the prompt neutrino contribution due to the recombination quark-parton model (RQPM) [31]. Solid line 4 shows the same for the prompt neutrino flux due to the quark-gluon string model (QGSM) [31] (see also [13, 17, 34]). Also shown are the two of the prompt neutrino predictions by Gelmini, Gondolo and Varieschi (GGV) [33] (curves 3 and 5).

Notice that recent evaluation of the prompt neutrino flux obtained with the dipole model (DM) [35], is rather close to the QGSM prediction at $E_\nu \gg 10^8$ GeV, keeping in mind that the theoretical uncertainty absorbs a difference of the DM and QGSM fluxes.

The prompt neutrino fluxes at $E_\nu = 100$ TeV are presented in Table III along with the upper limit on the astrophysical muon neutrino diffuse flux obtained in AMANDA-II experiment [4]. Note that the QGSJET-II+GH flux appears to be the most low flux of the conventional atmospheric neutrinos at high energies.

TABLE III: Atmospheric neutrino flux at $E_\nu = 100$ TeV vs. the AMANDA-II restriction for the $\nu_\mu + \bar{\nu}_\mu$ flux

| Model | $E_\nu^0\phi_\nu$, (cm$^{-2}$ s$^{-1}$ sr$^{-1}$) GeV |
|-------|-----------------------------------------------|
| conventional $\nu_\mu + \bar{\nu}_\mu$: |
| QGSJET-II + ZS | $1.20 \times 10^{-8}$ |
| QGSJET-II + GH | $1.11 \times 10^{-8}$ |
| prompt $\nu_\mu + \bar{\nu}_\mu$: |
| VZ [32] | $8.12 \times 10^{-8}$ |
| RQPM [31] | $4.61 \times 10^{-8}$ |
| QGSM [31] | $1.22 \times 10^{-8}$ |
| AMANDA-II upper limit [4] | $7.4 \times 10^{-9}$ |

IV. SUMMARY

The calculations of the high-energy atmospheric muon neutrino flux demonstrate rather weak dependence on the primary spectrum models in the energy range $10^{-4} - 10^5$ GeV. However the picture seems to be less steady because of sizable flux differences originated from the models of high-energy hadronic interactions. As it can be seen by the example QGSJET-II and SIBYLL 2.1, the major factor of the discrepancy is the kaon production in nucleon-nucleus collisions.

A common hope that atmospheric muon fluxes might be reliable tool to promote the discrimination between the hadronic interaction models seems to be rather
weakly depends on the zenith angle (near neutrinos origin. of the atmospheric muons, despite on their common to strong factor in comparison with that for production the kaon yield in nucleon-nucleus interactions is more illusive as the key differences in the $\pi/K$ production impact variously on the neutrino flux and muon one. For the high-energy neutrino production at the atmosphere the kaon yield in nucleon-nucleus interactions is more strong factor in comparison with that for production of the atmospheric muons, despite on their common to neutrinos origin.

Inasmuch as the atmospheric prompt neutrino flux weakly depends on the zenith angle (near 100 TeV), one may refer the AMANDA-II restriction just to the prompt neutrino flux model. Thus one may consider both RQPM and QGS to be consistent with the AMANDA-II upper limit for diffuse neutrino flux.

We thank V. A. Naumov for helpful discussions. We are grateful to T. Pierog for clarifying comments concerning the codes of hadronic interaction models.
