Abstract

We report superconductivity in single crystals of the new iron-pnictide system BaFe$_{1.90}$Pt$_{0.10}$As$_2$ grown by a self-flux solution method and characterized via x-ray, transport, magnetic and thermodynamic measurements. The magnetic ordering associated with a structural transition at 139 K present in BaFe$_2$As$_2$ is completely suppressed by substitution of 5% Fe with Pt and superconductivity is induced at a critical temperature $T_c = 23$ K. Full diamagnetic screening in the magnetic susceptibility and a jump in the specific heat at $T_c$ confirm the bulk nature of the superconducting phase. All properties of the superconducting state—including the transition temperature $T_c$, the lower critical field $H_{c1} = 200$ mT, the upper critical field $H_{c2} \approx 65$ T, and the slope $\partial H_{c2}/\partial T$—are comparable in value to those found in other transition metal-substituted BaFe$_2$As$_2$ series, indicating the robust nature of superconductivity induced by substitution of Group VIII elements.

(Some figures in this article are in colour only in the electronic version)

1. Introduction

The recent discovery of high-temperature superconductivity in iron-based pnictide compounds has attracted much interest among the condensed matter community, providing both a new angle for understanding the physics of unconventional superconductivity in other materials such as the copper-oxides, heavy-fermion intermetallics, etc, and an entire new family of superconducting materials of fundamental and technological interest. The highest $T_c$ achieved so far in these materials is $\sim 55$ K in SmO$_{1-x}$F$_x$FeAs [1] and (Ba, Sr, Ca) FeAsF [2, 3]. Oxygen-free FeAs-based compounds with the ThCr$_2$Si$_2$-type (122) structure also exhibit superconductivity with transition temperatures reaching $\sim 37$ K, induced by chemical substitution of alkali or transition metal ions [4–7], the application of large pressures [8–11], or lattice strain [12].

It is widely believed that suppression of the magnetic/structural phase transition in these materials, either by chemical doping or high pressure, is playing a key role in stabilizing superconductivity in the ferropnictides [13–15]. For instance, superconductivity has been induced by partial substitution of Fe by other transition metal elements from the Fe, Co and Ni groups in both the 1111 [16–18] and 122 compounds [6, 7, 19]. For the 122 phase, superconductivity has been induced by substituting Fe with not only 3$d$-transition metals such as Co and Ni, but also some of the 4$d$- and 5$d$-transition metals. Superconductivity with $T_c$ as high as 25 K has been observed in BaFe$_{2-x}$Co$_x$As$_2$ [20, 21] and BaFe$_{2-x}$Rh$_x$As$_2$ [22], and near 20 K in BaFe$_{2-x}$Ni$_x$As$_2$ [23, 15] and BaFe$_{2-x}$Pd$_x$As$_2$ [22] compounds. Recently, Ru and Ir substitution for Fe were also shown to induce superconductivity in polycrystalline SrFe$_2$As$_2$ samples [24, 25], leaving only Os and Pt substitutions from the Group VIII elements uninvestigated.

Here we report the first case of superconductivity induced by Pt substitution in the FeAs-based family, presenting the
observation of superconductivity at 23 K in BaFe$_{1.98}$Pt$_{0.10}$As$_2$. We present details of the synthesis and characterization of single crystals of this material via single-crystal x-ray diffraction, electrical resistivity, magnetic susceptibility and specific heat experiments.

2. Experiment

Single-crystalline samples of BaFe$_{2-x}$Pt$_x$As$_2$ were grown using the FeAs self-flux method [19]. Fe and Pt were first separately pre-reacted with As via the solid-state reaction of Fe (99.999%)/Pt (99.99%) powder with As (99.99%) powders in a quartz tube under partial Ar pressure. The precursor materials were mixed with elemental Ba (99.95%) in the ratio of FeAs:PtAs:Ba = 4–2x:2x:1, placed in an alumina crucible and sealed in a quartz tube under partial Ar pressure. The mixture was heated to 1150 °C, slow-cooled to a lower temperature and then quenched to room temperature. Typical dimensions of the as-grown single-crystal specimen of BaFe$_{1.98}$Pt$_{0.10}$As$_2$ are 0.1 × 1 × 2 mm$^3$. Structural properties were characterized by single-crystal x-ray-diffraction and Rietveld refinement (SHELXS-97). Chemical analysis was obtained via both energy- and wavelength-dispersive x-ray spectroscopy, showing proper stoichiometry in all specimens reported herein and no indication of impurity phases. Resistivity (ρ) samples were prepared using gold wire/silver paint contacts made at room temperature, yielding typical contact resistances of ∼1 Ω. Resistance measurements were performed using the standard four-probe AC method, with excitation currents of 1 mA at higher temperatures that were reduced to 0.3 mA at low temperatures to avoid self-heating, all driven at 17 Hz in a Quantum Design PPMS equipped with a superconducting magnet. Magnetic susceptibility (χ) and magnetization were measured using a Quantum Design SQUID magnetometer, and specific heat was measured with a Quantum Design PPMS cryostat using the thermal relaxation method.

3. Results

3.1. Crystallographic parameters

Table 1 shows the crystallographic parameters determined by single-crystal x-ray-diffraction at 250 K in BaFe$_{1.98}$Pt$_{0.10}$As$_2$. A Bruker Smart Apex2 diffractometer with Mo Kα radiation, a graphite monochromator with monocap collimator, and a CCD area detector were used for this experiment. The structure was refined with SHELXL-97 software using 1033 measured reflections, of which 115 were unique and 108 observed. The final residuals were $R_1 = 1.95\%$ for the observed data and $wR_2 = 4.46\%$ for all data. Fe and Pt atoms were found to reside in the same site with a refined Fe:Pt ratio of 0.953(4):0.047(4), giving the exact formula BaFe$_{1.9868(8)}$Pt$_{0.049(8)}$As$_2$ from x-ray analysis. Refinement data for BaFe$_2$As$_2$ determined by powder diffraction are adopted from [26] for comparison. As shown in table 1, the c-axis and the c/a ratio shrink due to Pt substitution, while the a-axis and the unit cell volume expand as compared to undoped BaFe$_2$As$_2$. Of note, the relative height of As above the Fe lattice (z-parameter) and the corresponding As–Fe–As bond angles change very little with Pt substitution.

3.2. Electrical resistivity

Figure 1(a) presents the comparison of the in-plane resistivity $\rho(T)$ of single crystals of BaFe$_{2-x}$Pt$_x$As$_2$ with $x = 0$ and 0.1 in zero applied magnetic field (data are presented after normalizing to room temperature). As shown, $\rho(T)$ data for BaFe$_2$As$_2$ exhibit metallic behavior, decreasing with temperature from 300 K before exhibiting a sharp kink at $T_0 = 139$ K, where a structural phase transition (from tetragonal to orthorhombic upon cooling) is known to coincide with the onset of antiferromagnetic (AFM) order [26]. For $x = 0$, $\rho$ continues to decrease below $T_0$ without any trace of strain-induced superconductivity down to 1.8 K [12]. The drop in $\rho(T)$ below $T_0$ has also been observed in other 122 materials [23, 7, 20, 15], and likely arises due to the balance between the loss of inelastic scattering due to the onset of magnetic order and the change in carrier concentration associated with the transition at $T_0$. In the $x = 0.10$ sample, there is no indication of the $T_0$ transition in $\rho(T)$ down to the superconducting transition that onsets at $T_c = 23$ K and drops to zero resistance by 21.5 K, indicating a resistive transition width $\Delta T_c < 1.5$ K. The suppression of the resistive superconducting transition of BaFe$_{1.98}$Pt$_{0.10}$As$_2$ with the magnetic field $H$ applied parallel to the c-axis is illustrated in figure 2. The data are normalized to the normal-state resistance above $T_c$ for clarity. Applied magnetic fields cause a tiny negative magnetoresistance at 25 K ($\rho(H = 14$ T) $- \rho(H = 0)) / \rho(H = 0) \sim -0.35\%$. The

{}
superconducting upper critical field $H_{c2}(T)$, as determined by the 50% resistive transition temperature for each field, is shown in the inset of figure 2. The slope $\partial H_{c2}/\partial T$ is $-2.8$ T K$^{-1}$ in the range $T < 20$ K, which is comparable to values reported for other transition metal doped FeAs-based superconductors [27]. This agreement is rather remarkable, given that these superconductors have values of $T_c$ ranging from 10 K to more than 30 K [27]. A simple estimate using the Werthamer–Helfand–Hohenberg (WHH) approximation, $H_{c2}(0) \approx 0.691 \frac{\mu_0 H}{T} T_c$, yields a value of $\approx 45$ T for the orbital $H_{c2}(0)$. However, previous studies (see [27]) have shown a more linear dependence of $H_{c2}(T)$ toward lower temperature, which would extrapolate to a value $H_{c2}(0) \approx 65$ T for BaFe$_{1.9}$Pt$_{0.1}$As$_2$. In any case, the response of the superconducting state to applied $H$ seems insensitive to whether superconductivity has been stabilized by different transition metals substitution, applied pressure, or presumably strain, in the case of the undoped parent compounds. In contrast, hole doped SrFe$_2$As$_2$ and BaFe$_2$As$_2$ feature larger values of $\partial H_{c2}/\partial T$ [27].

3.3. Magnetic susceptibility and magnetization

Figure 3(a) presents the temperature dependence of magnetic susceptibility $\chi$ of BaFe$_{1.9}$Pt$_{0.1}$As$_2$ measured under zero-field-cooled (ZFC) conditions by applying a magnetic field of 100 mT along the $ab$-plane at low temperatures. As shown, $\chi$ is nearly temperature independent down to 23 K with no indication of a magnetic/structural transition. Below 23 K, $\chi(T)$ sharply drops to negative values due to Meissner screening. The inset of figure 3 presents the volume susceptibility $4 \pi \chi$ for both ZFC and field-cooled (FC) conditions under a 1.0 mT magnetic field applied along the $ab$-plane at low temperatures, in order to compare the level of diamagnetic screening due to superconductivity. There is a relatively sharp drop of ZFC susceptibility from a positive to negative value below $T_c = 23$ K (onset) consistent with the resistivity data. As shown, the superconducting volume fraction, as estimated by the fraction of full diamagnetic screening ($4\pi \chi = -1$), reaches 100% at $\approx 17$ K, indicating the full Meissner effect.

In order to study the magnetic response of the superconducting state, the magnetization was measured as a function of field. Figure 3(b) shows the isothermal ($T = 1.8$ K) magnetization $M(H)$ measured from ZFC conditions. Magnetization is nonlinear and irreversible with $H$ due to superconductivity, and it is evident that the apparent value of $H_{c2}$ is well in excess of 6 T, consistent with our resistivity studies. A minimum is observed in the low $H$ region in the virgin curve, as identified by the diagonal arrow in figure 3(b), indicating the lower limit of a superconducting lower critical field value $H_{c1} = 200$ mT.

3.4. Specific heat

Specific heat measurements were performed to verify the bulk thermodynamic nature of the superconducting transition in BaFe$_{1.9}$Pt$_{0.1}$As$_2$. Temperature dependent heat capacity data in zero magnetic field for BaFe$_{1.9}$Pt$_{0.1}$As$_2$ are plotted in figure 4. An abrupt shift in the smooth $C_p(T)$ curve below 21 K, indicated by the arrow, is consistent with the superconducting phase transition observed in both resistivity and low-field magnetization data. Both the superconducting temperature and the upper critical fields in BaFe$_{1.9}$Pt$_{0.1}$As$_2$ are high, thus making a reliable estimate of the normal-state electronic specific heat $\gamma$ difficult. For this reason we have determined $\Delta C_p/T_c$ rather than the more traditional quantity...
Figure 3. (a) Temperature dependence of the magnetic susceptibility $\chi(T)$ in BaFe$_{1.90}$Pt$_{0.10}$As$_2$ measured with a 100 mT field applied parallel to the crystallographic basal plane following zero-field-cooled (ZFC) conditions. Inset: volume magnetic susceptibility at 1 mT for both ZFC and field-cooled (FC) conditions. (b) Magnetization of BaFe$_{1.90}$Pt$_{0.10}$As$_2$ as a function of applied field at 1.8 K, with $H$ applied in-plane. The loop has a large open-ended area indicating values of $H_c^2$ well in excess of 6 T. Demagnetization effects due to sample geometry have been corrected for both $\chi(T)$ and $M(H)$ data.

$\Delta C_p / \gamma T_c$. Due to finite widths of superconducting transitions, $\Delta C_p / T_c$ and $T_c$ values are determined from the plots of $C_p / T$ versus $T$ shown in the inset of figure 4 in an enlarged view using an isentropic construction, as done previously [28]. Data for $H = 10$ T (red square symbols), in which the anomaly due to superconductivity has been shifted to lower temperature, serve as the lower line for this analysis. The vertical distance between the up and down arrow gives the value of $\Delta C_p / T_c \approx 20 \text{ mJ mol}^{-1} \text{K}^{-1}$. Assuming the BCS weak-coupling approximation $\Delta C_p / \gamma T_c = 1.43$ and 100% superconducting volume, the value of $\gamma$ can be estimated to be about $14 \text{ mJ mol}^{-1} \text{K}^{-2}$, which is comparable to that found in other transition metal-doped BaFe$_2$As$_2$ superconductors [29]. For $x = 0$ in [26], a $C_p / T$ versus $T^2$ plot between 3.1 K and 14 K gives $\gamma = 16(2) \text{ mJ mol}^{-1} \text{K}^{-2}$, corresponding to a Debye temperature of $\Theta_D = 134(1)$ K. In [28], the values of $\Delta C_p / T_c$ measured for K, Co, Ni, Rh, and Pd doped BaFe$_2$As$_2$ superconductors have been shown to scale with $T_c$, regardless of the value of $T_c$ or the relative doping position (under or over doped) with respect to the maximum $T_c$. Surprisingly, the corresponding value of $\Delta C_p / T_c \approx 20 \text{ mJ mol}^{-1} \text{K}^{-1}$, taken at 20 K for BaFe$_{1.90}$Pt$_{0.10}$As$_2$, also falls in line with this trend, expanding this interesting relation to include another 5d-transition metal-doped system.

4. Discussion

Although the detailed phase diagram is yet unknown, the superconducting properties of this new member of the superconducting FeAs-based materials look to be strikingly similar to those observed in the other related compounds. The widely perceived picture is that pairing occurs through the interpocket scattering of electrons via exchange of antiferromagnetic spin fluctuations [30]. By doping electrons or holes into the parent phase, magnetic order is gradually destroyed and the short-range order provides a wide spectrum of spin fluctuations which may be responsible for pairing between electrons. Alternatively, magnetic order and superconductivity may compete to gap similar parts of the Fermi surface, with superconductivity only appearing when magnetic order is suppressed. It is certain that superconductivity is associated, directly or indirectly, with the suppression of magnetic order in the FeAs-based 122 systems, and an understanding of the generalized phase diagram must be an integral part of any explanation of the physics of these materials.
This picture can certainly give a qualitative explanation for the generally similar occurrence of superconductivity via doping of different species of Group VIII elements (including Co, Rh, Ir, Ni, Pd, and now Pt) into the 122 parent compounds. However, subtle details and differences among these different series may hold important information regarding the specific mechanism(s) by which magnetic order is suppressed and superconductivity is optimized. For instance, in BaFe$_{2-x}$Co$_x$As$_2$ the maximum $T_c$ is found at $x \approx 0.15$ [21, 31], whereas in BaFe$_{2-x}$Ni$_x$As$_2$ the maximum $T_c$ occurs at approximately $x \approx 0.10$ [23, 15]. This appears to be consistent with simple d-electron counting, and hence charge doping, however it is not clear that simple scaling of different phase diagrams by electron counting works in all cases [19]. Another interesting aspect of the superconductivity in 122 materials is the similarity of maximum $T_c$ values, typically reaching 20–25 K regardless of the transition metal substituent [29, 25]. While this is thus far true in all Ba-based compounds, the trend is broken in Sr-based 122 systems such as SrFe$_{2-x}$Pd$_x$As$_2$ [25] and SrFe$_{2-x}$Ni$_x$As$_2$ [19], which both exhibit reduced maximum values of $T_c$ closer to ~10 K. While the value of $T_c$ in BaFe$_{1.98}$Pd$_{0.02}$As$_2$ is in line with most other transition metal doped BaFe$_2$As$_2$ superconductors, it is slightly higher than the maximum $T_c$ of ~18 K found in the closely related series BaFe$_{2-x}$Pd$_x$As$_2$ [22]. Although differences in maximal $T_c$ values could arise for many different reasons, intrinsic variations of $T_c$ in different doping series may be an important indicator of the nature of pairing in this family of materials. Because it is known that annealing treatments of as-grown crystals of SrFe$_{2-x}$Ni$_x$As$_2$ result in a significant enhancement in superconducting transition temperatures [32], it will be important to investigate the role of crystal quality on variations in $T_c$ values in these systems.

Finally, because Os is now the only remaining element of the Fe, Co and Ni transition metal groups to be investigated, it will be surprising if Os substitution does not also induce superconductivity in BaFe$_2$As$_2$ or SrFe$_2$As$_2$ systems. Future work will investigate this question.

5. Summary

In summary, single crystals of the 5d-transition metal Pt-substituted BaFe$_2$As$_2$ were successfully synthesized and shown to become bulk superconductors, leaving only one remaining element in the Group VIII transition metals to be shown to induce superconductivity in the iron-pnictide family of materials. Transport, magnetic and thermodynamic studies have revealed superconductivity below $T_c = 23$ K in BaFe$_{1.98}$Pd$_{0.02}$As$_2$ to be of a bulk nature and robust against applied magnetic field, with estimates of upper critical field values near ~65 T. The similarity in superconducting properties between the substitution series of different transition metals suggests that similar underlying physics is at play in stabilizing superconductivity in this family of materials.
