(Dated: February 17, 2022)

We propose a mechanism for the observed stacking charge order in the quarter-filled ladder compound NaV$_2$O$_5$. Via a standard mapping of the charge degrees of freedom onto Ising spins we explain the stacking order as a result of competition between couplings of the nearest and next-nearest planes with the 4-fold degenerate super-antiferroelectric in-plane order.

There has been a great interest in recent years from both theorists and experimentalists in the insulating transition-metal compound NaV$_2$O$_5$ [1]. This material provides a rather unique example of a correlated electron system, where the interplay of charge and spin degrees of freedom results in a phase transition into a phase with coexistent spin gap and charge order. NaV$_2$O$_5$ is the only known so far quarter-filled ladder compound [2]. Each individual rung of the ladder is occupied by single electron which is equally distributed between its left/right sites in the disordered phase (see Fig. 1). At $T_c = 34$ K this compound undergoes a phase transition when a spin gap opens, accompanied by charge ordering [3, 4, 5, 6]. The experimentally observed two-dimensional (2D) long-range charge order in NaV$_2$O$_5$ [5] (the $ab$-plane order is shown in Fig. 1) is super-antiferroelectric (SAF), as we have pointed out recently [7]. The theory of spin-SAF transition put forward by us [7, 8, 9] is adequate to account for, even quantitatively, various aspects of the transition in NaV$_2$O$_5$. It deals, however, with a single ($ab$) plane, leaving aside the question of charge ordering along the third ($c$) direction. The phase transition in NaV$_2$O$_5$ quadruples the unit cell in $c$-direction (the supercell of the ordered phase is $2a \times 2b \times 4c$), and the recent X-ray experiments [2, 3] revealed peculiar ordering patterns in $c$-direction (stacking order) of the super-antiferroelectrically charge-ordered planes. Here we present a model which provides the explanation for the observed stacking order in NaV$_2$O$_5$.

An insulating quarter-filled ladder system, with electrons localized on the rungs of the ladder, can be mapped on an effective spin-pseudospin model, where the Ising pseudospin ($T^x$) represents left/right positions of the charge on a given rung, similar to the standard pseudospin approach to the order-disorder-type phase transitions [10]. The 2D effective spin-pseudospin Hamiltonian, able to describe the spin-SAF transition in NaV$_2$O$_5$, was given in [7]. Since the present work is concerned with the physics of the charge order, we will discuss here exclusively the Ising sector of the full spin-pseudospin model.

Within the spin-pseudospin formalism, the $ab$-plane of coupled ladders can be mapped on the effective lattice shown in Fig. 2 which in its turn we smoothly map onto a more conventional square lattice. It is then easy to identify the charge order in the $ab$-plane (see Figs. 1 and 4 below) as the SAF phase [11] of the 2D nearest neighbor (nn) and next-nearest neighbor (nnn) Ising model, shown in Fig. 3. Since the Ising couplings $J_2 = J_3, J_1, J_2$ originate from the Coulomb repulsion, we assume them to be antiferro (AF), i.e., $J_2 > 0$. SAF is the ground state of the 2D nn and nnn Ising model, if

$$J_1 + J_2 > |J_2|, \quad \text{and} \quad J_{1,2} > 0 \quad (1)$$

The SAF state can be viewed as two superimposed antiferromagnetically ordered sublattices (circled/squared sites shown in the right panel of Fig. 3), and it is 4-fold degenerate, since each of these sublattices can be flipped independently.

Some possible patterns of the stacking charge order in NaV$_2$O$_5$, determined from the X-ray experiments [3], are shown in Fig. 4. In terms of the effective Ising model this translates into the 3D pseudospin ordering patterns depicted in Fig. 5. To explain the mechanism of these types of order, let us consider the “minimal” 3D nn and nnn Ising model with the Hamiltonian

$$H = \frac{1}{2} \sum_{k,l} J_{kl} T_k^x T_l^x \quad (2)$$

where the bold variables denote lattice vectors. The sum includes spins on the nn sites coupled via $J_2, J_3$ and on the nnn sites coupled via $J_{1,2,4}$ (cf. Figs. 3, 4). This model reduces to a more familiar 3D ANNNI model [12] when the diagonal couplings $J_{1,2}$ are absent. We will be interested in the case of the plaquette couplings satisfying

\begin{figure}[h]

\caption{NaV$_2$O$_5$: ladders in the $ab$-plane. In the disordered phase each electron is equally distributed between left/right sites on a given rung (left panel), while below $T_c$ electrons (filled black circles) order as shown in the right panel.}
\end{figure}
FIG. 2: $ab$-plane of coupled ladders mapped onto an effective 2D lattice. A vertical line and a dot represent a single ladder and its rung. The Ising pseudospin (up/down) represents the position (left/right) of the electron on a given rung.

FIG. 3: Couplings on an elementary plaquette of the 2D nn and nnn Ising model (left) and an example of the SAF order (right). An plaquette on the square lattice corresponds to the encircled region in Fig. 2.

Note, that the four patterns A-D of the SAF state can be divided into two pairs of the “AF counterparts” (A, B) and (C, D) in the sense that in the presence of an AF coupling between two SAF-ordered planes, the counterparts A and B (or C and D) minimize the energy without inter-plane frustrations (cf. Fig. 5).

From energy considerations one finds that, if $J_4 > |J_3|/2$, the model has a 16-fold degenerate ground state composed of the SAF-ordered planes stacked with a period of four lattice spacings in $z(c)$-direction. We will denote this 3D order as SAF×4. (Note that the in-plane SAF phase itself can take either $2 \times 1$ pattern, or $1 \times 2$.) The number of frustrated inter-plane bonds ($J_4$) in the SAF×4 phase is 8 per 4 stacked elementary cubes of the lattice (in average 2 $J_3$-bonds per elementary cube). This phase can be realized via four 4-fold degenerate stacking patterns:

- $\langle AABB \rangle$, type I
- $\langle ACBD \rangle$, type II
- $\langle ADBC \rangle$, type III
- $\langle CCDD \rangle$, type IV.

4-fold degeneracy of each of these stacking patterns comes from translations along the stacking direction, or, in terms of the above notations, from cyclic permutations inside the angular brackets. So, the two particular realizations of the SAF×4 state shown in the left and right panels of Fig. 5 belong to the patterns II and IV, respectively.

If $J_4 < |J_3|/2$ the model can have two possible 4-fold degenerate ground states SAF×1 or SAF×2, depending on the sign of $J_3$. If the nn-interplane coupling is AF $J_3 > 0$, the model’s ground state SAF×2 can be realized via two 2-fold degenerate stacking patterns $\langle AB \rangle$ or $\langle CD \rangle$. For a ferromagnetic nn-interplane coupling $J_3 < 0$, the 4-fold degenerate ground state SAF×1 is simply one of the four possible SAF patterns stacked in $c$-direction. In each of the phases SAF×1 or SAF×2 there are 4 frustrated inter-plane bonds ($J_4$) per elementary cube of the lattice. Thus, to summarize the ground-state phases:

$$J_4 > |J_3|/2 : \text{SAF}\times 4$$
$$J_4 < J_3/2 : \text{SAF}\times 2$$
$$J_4 < -J_3/2 : \text{SAF}\times 1$$
energy stacking faults, e.g., \(\{\text{ordering}\ (I-IV)\) together with the experimental findings \[6\] lead us to the conclusion that at low temperature faults of the type \((\text{III})\) prevail. This result to energy consideration, we can conclude that at low temperature faults of the type \((\text{III})\) prevail, which are of course many other possible stacking faults (with higher energies) which we will not discuss. From an energy consideration, we can conclude that at low temperature faults of the type \((\text{III})\) prevail. This result together with the experimental findings \[6\] lead us to the conclusion that in NaV\(_2\)O\(_5\) all four possible types of ordering (I-IV) occur indiscriminately, with minimal-energy stacking faults, e.g., \(\langle\text{II}\rangle \bullet \langle\text{I}\rangle \bullet \langle\text{III}\rangle \bullet \langle\text{IV}\rangle\).

Above we assumed \(J_3 < 0\), which might appear odd, since all Ising couplings originate from the Coulomb repulsion, i.e., they are antiferro. In fact such ferromagnetic coupling is an effective coupling replacing interactions between several charges in order to keep the model “minimal”\(^1\) In this sense \(J_4\) is an effective coupling as well, both \(J_3\) and \(J_4\) should be viewed as phenomenological parameters whose signs and relative strengths are chosen to agree with experiments. We can however suggest a simple mechanism resulting in an effective \(J_3 < 0\). Let us consider two nn ladders (two chains in terms of the effective lattice shown in Fig. \[2\]) separated by a lattice unit \(c\) in the stacking direction. On a single plaquette in the b-plane, let us take into account the nn couplings \(J_1\) (along (0, 1, 0)-direction) and \(J_3\) (along (0, 0, 1)-direction), with \((J_1 > J_3)\), in addition to a nnn-coupling \(J_4\) along plaquette’s diagonals (along (0, ±1, 1)-directions). A simple analysis shows that the two nearest stacked chains tend to align ferromagnetically in \(c\)-direction when \(J_4 > J_3/2\). We can therefore take \(J_3 = J_4 - 2J_3\) as the single effective nn coupling, as shown in Fig. \[5\]. Considering the actual lattice distances in NaV\(_2\)O\(_5\) and the distance-dependence of the Coulomb repulsion one finds \(J_3 < 0\).

Experiments on NaV\(_2\)O\(_5\) under pressure \[13\] show that the in-plane SAF charge order is robust and does not change, while at the pressure \(P_c = 0.92\) GPa a transition of the ground state charge order from SAF \times 4 into SAF \times 1 occurs. Thus, in NaV\(_2\)O\(_5\) the pressure dependence of in-plane couplings is “non-critical”, i.e., condition \((\text{II})\) is satisfied, while the ratio \(\kappa \equiv J_4/J_3\) of the couplings between planes is more sensitive to pressure. As follows from \[9\] this ratio reaches the frustration point \(\kappa_c = -1/2\) at \(P_c\), and then the ground state changes.\(^2\)

Another very interesting feature of the charge ordering under pressure in NaV\(_2\)O\(_5\) is the existence of a region with numerous higher-order commensurate superstructures SAF \times \(\frac{m}{n}\) (where \(m, n\) are integers), i.e., a devil’s staircase region above \(P_c\) on the temperature-pressure plane \[13\]. Ohwada and co-workers noticed resemblance between the experimental phase diagram and that of the 3D ANNNI model. (For reviews on that model see, e.g.,

---

\[1\] For single layer a “truly minimal” model, still having the SAF phase, would be that with \(J_2 = 0\). In this case it consists of two decoupled superimposed (AF) Ising lattices. Then our model \([4]\) with nn and nnn interactions between layers reduces to two identical inter-penetrating decoupled 3D ANNNI models, cf. Figs. \[6, 11\]. Let us call this limit the A\(\otimes\)A model for brevity.

\[2\] In connection to what was said before about \(J_3\), we should point out that experiments do not rule out \(J_3 > 0\) at ambient pressure since SAF \times 4 order is insensitive to the sign of \(J_3\), as long as \((\text{III})\) is satisfied. Then \(J_3\) must decrease under pressure such that at \(P_c\) it is already ferromagnetic and \(\kappa = \kappa_c\). We find such a possibility rather exotic, and will not consider it here. Note also that if \(J_3 > 0\) at ambient pressure, the above analysis of energies of stacking faults should be modified accordingly.
However an explanation of the charge ordering in NaV$_2$O$_5$ in the framework of the ANNNI model is incorrect, as the latter cannot have the in-plane SAF order in principle. The minimal model to reproduce the observed experimental results is what we call the A⊗A model (see footnote 1): two superimposed square lattices create the observed overall SAF order in the individual layers, while the period of the charge order in the stacking direction is the same as in a single 3D ANNNI model.

Considering the geometry of the original NaV$_2$O$_5$ lattice, one can see that $J_\square$ is indeed rather small in comparison to $J_1$, so the minimal A⊗A model appears to be adequate for the description of the charge ordering in that compound.

The more complicated model (2) with $J_\square \neq 0$ and $\kappa_c$ satisfied, is expected, from mean-field considerations, to also show a sequence of commensurate phases originated from the frustration point $\kappa_c = -1/2$ separating the SAF×4 and SAF×1 ground states, similarly to the 3D ANNNI model. However to substantiate this suggestion, a separate study of the temperature phase diagram of (2) is warranted.

So far we have been discussing the charge in NaV$_2$O$_5$ in terms of Ising models. The full spin-pseudospin Hamiltonian of the problem is more involved $\mathbb{2}$, since it includes also a transverse field in the Ising sector plus coupling of the charge (Ising pseudospin) to the spin degrees of freedom. The present 3D extension of the Ising sector can be treated along the lines of our earlier analyses $\mathbb{3}$, $\mathbb{8}$, resulting in simultaneous appearance of the charge (Ising) order and spin gap.

Conclusions: We propose a mechanism for the stacking charge order in NaV$_2$O$_5$. It is a result of competition between couplings of the nearest and next-nearest planes with the 4-fold degenerate SAF in-plane order. The simplest effective model resulting in the observed charge ordering patterns consists of two decoupled interpenetrating 3D ANNNI models (the A⊗A model). The same arguments suggest a weak diagonal $J_2$, which is, however, reinforced effectively due to the bilinear spin-pseudospin coupling in NaV$_2$O$_5$ $\mathbb{3}$.

We thank S. Grenier for providing us with Fig. 4 and helpful communications. This work is supported by the German Science Foundation.
