Abstract Our previous work indicated that apolipoprotein (apo) E4 assumes a more expanded conformation in the postprandial period. The postprandial state is characterized by increased VLDL lipolysis. In this article, we tested the hypothesis that VLDL lipolysis products increase VLDL particle fluidity, which mediates expansion of apoE4 on the VLDL particle. Plasma from healthy subjects was collected before and after a moderately high-fat meal and incubated with nitroxyl-spin labeled apoE. ApoE conformation was examined by electron paramagnetic resonance spectroscopy using targeted spin probes on cysteines introduced in the N-terminal (S76C) and C-terminal (A241C) domains. Further, we synthesized a novel nitroxyl spin-labeled cholesterol analog, which gave insight into lipoprotein particle fluidity. Our data revealed that the order of lipoprotein fluidity was HDL<LDL<VLDL< VLDL+lipoprotein lipase. Moreover, the conformation of apoE4 depended on the lipoprotein fraction: VLDL-associated apoE4 had a more linear conformation than apoE4 associated with LDL or HDL. Further, by changing VLDL fluidity, VLDL lipolysis products significantly altered apoE4 into a more expanded conformation.**

Our studies indicate that after every meal, VLDL fluidity is increased causing apoE4 associated with VLDL to assume a more expanded conformation, potentially enhancing the pathogenicity of apoE4 in vascular tissue.—Tetali, S. D., M. S. Budamagunta, C. Simion, L. J. den Hartigh, T. Kalai, K. Hideg, D. M. Hatters, K. H. Weisgraber, J. C. Voss, and J. C. Rutledge. VLDL lipolysis products increase VLDL fluidity and convert apolipoprotein E4 into a more expanded conformation. J. Lipid Res. 2010. 51: 1273–1283.

Supplementary key words lipoprotein fluidity • postprandial state • structural conformation • very low density lipoprotein

Apolipoprotein E (apoE), a 34 kDa protein that is important in lipid metabolism and cholesterol transport, has three common alleles (e2, e3, and e4). ApoE polymorphisms influence the risk of atherosclerotic cardiovascular disease and neurodegenerative disorders (1). ApoE3 binds preferentially to HDL and apoE4 to VLDL (2). ApoE contains a 22 kDa N-terminal domain (residues 1–191) and a 10 kDa C-terminal domain (residues 222–299) separated by a protease-sensitive loop (3). ApoE4 shows a more pronounced domain interaction or closed conformation than the other apoE isoforms because it has Arg-112, which enables Arg-61 in the N-terminal domain to interact with Glu-255 in the C-terminal domain, a feature responsible for the preferential association of apoE4 with VLDL (4, 5).

Upon binding to lipid, apolipoproteins undergo conformational rearrangements (6, 7) that affect their function. The association of apoE isoform–dependant postprandial lipoprotein metabolism with vascular disease is not well understood. Previously, we reported that lipolytic products of VLDL reduce the intermolecular inter-

action of apoE4, i.e., the self-association of apoE4 via its C terminus (8); however, the mechanism for such effect was unknown. In this study, we used electron paramagnetic resonance (EPR) spectroscopy to investigate intramolecular interaction, i.e., domain interaction in apoE4 affected by VLDL lipolysis products. Our findings show that the conformation of apoE4 is modulated postprandially and is mediated by VLDL particle fluidity. These conformational changes may be important in lipoprotein-vascular cell binding and possibly in vascular injury.

MATERIALS AND METHODS

Materials for this work are as follows: streptokinase, ICN Pharmaceuticals (Costa Mesa, CA); vacutainers and venipuncture supplies, Fisher Scientific International (Hampton, NH); glass capillaries, VitroCom (Mountain Lakes, NJ); flat cell (catalog no. ES-LC11), JEOL (Tokyo, Japan); lipoprotein lipase, 5-doxo- and 16-doxystearic acid spin probes, and guanidine thiocyanate, Sigma-Aldrich (St. Louis, MO); (1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-methyl) methanethiosulfonate and 12-doxystearic acid, Toronto Research Chemicals (Toronto, Canada); titan gel electrophoresis supplies, Helena Laboratories (Beaumont, TX); dimyristoylphosphatidylcholine (DMPC), egg yolk phosphatidylcholines, extruder were from Avanti Polar Lipids (Alabaster, AL); and triolein, cholesterol oleate, cholesterol, and free fatty acids were from NuChek-Prep (Elysian, MN). α-Thrombin was from Hematologic Technologies (Essex Junction, VT), and Slide-A-Lyzer dialysis cassettes (MWCO 10,000) were from Pierce (Rockford, IL).

Expression and site-directed spin-labeling of apoE

Recombinant plasmids containing thioredoxin-his tagged apoE sequences in pET32a-NT were expressed in BL21 (DE3) Escherichia coli cells as described previously but with modifications (9, 10). The protein was purified with a Ni-affinity column, complexed with DMPC vesicles, and extruded through 100-nm polycarbonate membrane filters. The thioredoxin-his tag was cleaved from apoE with human α-thrombin. The apoE/DMPC complex was lyophilized, dispersed in 50 ml of methanol, and centrifuged at 6,000 g for 20 min at 4°C to remove the DMPC. The pellet was dissolved in denaturation buffer (6 M guanidine and 2× TBS), renatured, and assayed for protein content as described (10). The purity and integrity of the protein was tested by SDS-PAGE. The apoE mutants used for this study were apoE4 with two cysteine moieties substituted at amino acid positions 76 and 241 (76C-241C) and apoE3-like protein (R61T-76C-241C).

Human plasma samples

Healthy human subjects were recruited from the University of California, Davis. The study was approved by the Human Subjects Research Committee of the University of California, Davis. Written informed consent was obtained from each participant. The volunteers were fed a moderately high-fat meal (40% calories from fat), and blood was obtained by venipuncture into Vacutainer tubes containing streptokinase (1,500 units) or EDTA, before (fasting, 0 h) and 3.5 and 6 h after ingestion of the test meal (8).

Lipoprotein isolation by NaCl density gradient centrifugation

Blood samples were centrifuged at 1,750 g for 10 min at 4°C to separate plasma from cellular blood constituents. Lipoproteins were isolated by sequential flotation with minor modifications (11). Plasma was transferred into ultracentrifuge tubes (Beckman-Coulter), and 0.01% (w/v) Na2SO4 was added as a preservative. Plasma was diluted 1:2 in 196 mM NaCl and 0.25 mM EDTA (p = 1.0063) and centrifuged at 63,000 g for 30 min at 14°C to allow chylomicron flotation. The remaining plasma was spun at 285,000 g for 18 h at 4°C to isolate VLDL. The density of the remaining plasma was adjusted to 1.063 to isolate LDL and to 1.21 to isolate HDL and spun at 285,000 g for 18 h at 4°C for each lipoprotein fraction. Lipid fractions were dialyzed against 150 mM NaCl + 0.25 mM EDTA overnight at 4°C. Plasma and lipid fractions were stored at 4°C and used within 3 days after isolation. Triglyceride rich lipoprotein (TGR) containing both chylomicrons and VLDL were isolated by centrifuging the plasma samples at 285,000 g for 18 h at 14°C.

Lipoproteins were lipolyzed by incubation with bovine milk lipoprotein lipase (LpL) (3 U/ml) at 37°C for 30 min and assayed for nonesterified fatty acids. LDL cholesterol, HDL cholesterol, total cholesterol, triglycerides (TGs), and nonesterified fatty acids were quantified with an autoanalyzer.

Separation of lipoproteins by Titan gel electrophoresis

Equal amounts of spin-labeled apoE4 or apoE3-like protein (0.2 mg/ml) were incubated with fasting plasma, postprandial VLDL, or LpL-treated postprandial VLDL at 37°C for 1 h and applied (2 µl/lane) to Titan-agarose precasted gels. To assay the association of apoE with each lipoprotein class, lipoprotein bands on the gel were visualized by staining and destaining (8). HDL, LDL, and VLDL bands were excised from the gel, solubilized in 4.5 mol/l guanidine iso-thiocyanate at 65°C, and analyzed by EPR spectroscopy, and the quantity of spin-labeled apoE associated with the VLDL fraction was determined (8).

Samples with spin-labeled lipids

The 5-doxyl-, 12-doxyl, and 16-doxystearic acid (DSA) spin probes solubilized in ethanol were added to lipoproteins and mixed extensively by pipetting to ensure uniform equilibration of the probe with the sample. The final concentration of the 5-, 12-, and 16-DSA probes in the lipoprotein samples was 2 µmol/l. Spin-labeled probe/total cholesterol ratios were maintained at 1:650.

Synthesis of spin-labeled cholestanol

The synthesis of SL-cholesterol 3-[17-(1,5-dimethyl-hexyl)-3-hydroxy-10,13-dimethyl-hexadecahydro-cyclopenta[a]phenantren-2-ylidenemethyl]-2,2,5,5-tetramethyl-3-tetradecahydro-1H-pyrrrol-1-oxyl radical cholesterol (Fig. 1A) is described as follows. To a solution of 5a-cholestan-3-one (3.86 g, 0.01 mol) in methanol (30 ml), 10% NaOH solution (2 ml), and aldehyde (1.68 g, 0.01 mol) were added. The mixture was stirred at room temperature for 3 h, acidified with 5% H2SO4, and extracted with CHCl3 (5 × 20 ml). Lipid was washed with brine (2 × 20 ml), dried (MgSO4), and evaporated. The residue was purified by flash chromatography with hexane/ethanol to give the ketone 17-(1,5-dimethyl-hexyl)-2-(1-oxyl-2,2,5,5-tetramethyl-3-tetradecahydro-1H-pyrrrol-1-oxyl)-10,13-dimethyl-hexadecahydro-cyclopenta[a]phenantren-3-one radical. To a solution of ketone (2.69 g, 5.0 mmol) in absolute etha-nol (20 ml), NaBH4 (0.19 g, 5 mmol) was added at 0°C. The reaction mixture was allowed to warm up to room temperature. After 1 h at room temperature, the mixture was quenched with water (10 ml), the alcohol was evaporated, and the aqueous phase was extracted with CHCl3 (3 × 20 ml). The organic phase was dried (MgSO4), evaporated, and purified by flash chromatography to give the final product. The yield was 1.93 g (72%); mp 187–188°C; Rf 0.60 (CHCl3/2-propanol 2:1); MS, m/z (%) = 538 (M+), 508 (7), 465 (10), and 43 (100). Elemental analysis calculated for
Preparation of synthetic TG-rich emulsions

The TG-rich emulsions were prepared as previously described (12). Briefly, lipids composed of 69% triolein, 22% egg yolk phosphatidylcholine, 6% cholesteryl oleate, and varied concentrations of cholesterol (2-8%) were mixed together and then dried under a stream of nitrogen. The dried mixtures were resuspended in a small aliquot of 10 mM Tris-HCl buffer (pH 8.0) containing 0.1 M KCl and 1 mM EDTA and then emulsified in a bath sonicator at 50°C for an hour or until the homogenous emulsion was formed. Then, the emulsions were extruded using an extruder to form particles by passing 15 to 20 times through polycarbonate membrane of 100 nm pore size. After the extrusion, particles were assayed for their total triglyceride and cholesterol content. Further, the extruded particles were used for apoE binding assay on the day of preparation.

EPR spectroscopy

EPR measurements of apoE4 were performed with a JEOL X-band spectrometer fitted with a loop-gap resonator (8). Spin-labeled apoE in TBS (10 mM Tris, pH 7.4, 150 mM sodium chloride, and 0.005% sodium azide) to a final concentration of 0.2 mg/ml protein was added to plasma or lipoprotein fractions or VLDL spiked, as described in Ref. 8, with 0.5 mM of fatty acids [stearic (18:0), oleic (18:1), linoleic (18:2), or linolenic (18:3) acids], and the ratio between fatty acid and cholesterol content of lipoprotein was maintained at 1:2.6. The samples were loaded into one-sided sealed glass capillaries, incubated at 37°C for 1 h, and scanned by EPR. For all the samples, vehicle controls were used. The spectra were obtained by an average of three scans (2 min each) over 100 G at a microwave power of 2 mW and a modulation amplitude of 1 G at room temperature (20-22°C) or at 37°C. To assess the signal content in guanidine-extracted gel samples, a quartz flat cell was used, and the signal-averaged spectra from six 20-G scans (20 s each) over the central (m_0 = 0) line were recorded.

Order parameters for the spectra of samples containing spin-labeled lipids were calculated as described (13). For samples containing the 5-DSA label, the order parameter S was calculated as

$$S = \frac{(T_{||} - T_{\perp})}{(T_{||} + 2T_{\perp})}$$

Where C = 1.4 - 0.053 (T_{||} - T_{\perp}). For the unresolved T_{||} in the 12- and 16-DSA spectra, T_{||} was estimated from T_{||} = 44.5 - 2T_{\perp}.

Statistics

All statistical analyses were performed using ANOVA as guided by SigmaStat software, with pairwise comparisons made using the Holm-Sidak method. Where applicable, data are reported as mean ± SD. Statistical significance was reported for P < 0.001, as indicated.

RESULTS

Selection of apoE4 (76C-241C) to study conformational changes of apoE

Mutagenesis studies (14, 15) have demonstrated that apoE self-associates via a hydrophobic face along the C-terminal domain helix. This intermolecular interface is largely disrupted when apoE binds lipids, as measured by the loss dipolar interaction of spin labels placed at position 264 (8, 10, 16). The reduced intermolecular interaction as measured by spin-labeled apoE4(264C) proved to be a useful marker for apoE4 binding to plasma lipids collected pre- and postprandially (8). To explore the influence of lipolysis on the conformation and distribution of apoE4, we used a previously developed intramolecular domain interaction indicator construct (76C-241C) to monitor conformational differences between apoE3 and apoE4 that are predicted to be important in mediating their functional differences (10). In artificial lipid systems [DMPC, emulsions, and dipalmitoylphosphatidylcholine (DPPC)], where elevated concentrations facilitate spin dilution, no evidence of intermolecular spin interaction (arising from labels within 2.0 nm of one another) is observed from either position 76 or position 241 (10, 16).

In the lipid-free state, apoE4 is distinguished by domain interaction between the N-terminal bundle and the C-terminal helix, which is responsible for its binding preference for VLDL (10, 16). Lipid-bound apoE has an extensive helical structure but adopts alternate conformations depending on lipid composition and particle size. For example, lipid-bound apoE3 with extended helical segments has been found on the edge of phospholipid (DMPC or 1-palmitoyl-2-oleoylphosphatidylcholine) particles (17, 18). A similar conformation of apoE4 has been found on TG-rich emulsions (10). However, as shown by X-ray crystallography (19, 20), apoE4 on DPPC particles has a double-helix structure with a hairpin near the midpoint of the protein sequence. EPR measurements showed that proximity of amino acids 76 and 241, indicating domain interaction in the lipid-free protein, is maintained in the DPPC-bound state (16). Thus, the 76-241 pair is useful for assessing domain interaction in the lipid-free protein and for distinguishing between a hairpin or extended helical conformation in the lipid-bound state.

The indicator constructs, which contain cysteines at amino acids 76 and 241, detect the differences in the distance between the two regions of apoE when these sites are covalently modified with spin labels and assessed by EPR spectroscopy (10). Because apoE3 has an endogenous cysteine that would react with a spin label, we used an apoE3 indicator construct with an R61T mutation (10). This construct behaves structurally and functionally like apoE3 because the mutation abolishes domain interaction (21). Specific labeling of apoE4 (which has no cysteines) is achieved by reacting the sulfhydryl-specific nitroxide label (MTS-SL) with apoE4 containing the substitutions S76C and A241C (Fig. 1B). Based on the level of dipolar interaction evident in the EPR spectrum in apoE4 containing these two spin-labeled side chains, the relative distance between the N- and C-terminal domains is evident. Because apoE3 has Cys112, we used an apoE4-like protein (Fig. 1C) to determine the isoform-dependence of apoE’s response to lipolysis (4, 10).
were separated by agarose gel electrophoresis. The extent of binding and relative distribution of exogenously added apoE3-like protein or apoE4 with plasma lipoprotein fractions, VLDL, LDL, or HDL, was determined by assaying the amount of spin-labeled proteins by EPR spectroscopy (8). Like the native proteins, apoE3-like protein bound preferentially to HDL (49% vs. 27% to LDL and 31% to VLDL) (Fig. 2B), and apoE4 bound predominantly to VLDL (56% vs. 16% to HDL and 27% to LDL).

Comparison of apoE conformations on lipoprotein particles

To assess the conformation of apoE on lipoprotein fractions, we incubated fasting plasma from healthy volunteers with spin-labeled apoE3-like or apoE4 for 1 h at 37°C before scanning. Incubation of apoE3-like protein with HDL or VLDL elicited similar reductions in spectral broadening, resulting in spectra with larger amplitudes (Fig. 2A). The spectra in Fig. 2A are plotted so that each represents the same number of spins. The R61T mutation increased the distance between the domains in the lipid-free protein, resulting in less spectral broadening, as shown previously (10). Postprandial plasma decreased the dipolar broadening of apoE4. The effect was greatest at 3.5 h, but the broadening was less than that in the apoE3-like sample. This suggests that this population of apoE4 retains some of the conformational features of its lipid-free state in plasma. In contrast, the apoE3-like protein maintained a more open conformation both in the lipid-free state and in plasma. This difference allows a systematic investigation of apoE isoform-specific behavior in the postprandial state. Fasting and postprandial serum lipid values of six of the healthy volunteers who participated in this study are listed in Table 1.

Preferential distribution of spin-labeled apoE3-like protein and apoE4 with plasma lipoproteins

To determine if the apoE3-like and apoE4 mutants have binding preferences similar to those of the native proteins, we incubated fasting plasma from healthy volunteers with spin-labeled apoE3-like protein (61T-76C-241C) or apoE4 (76C-241C) for 1 h at 37°C. The samples were separated by agarose gel electrophoresis. The extent of binding and relative distribution of exogenously added apoE3-like protein or apoE4 with plasma lipoprotein fractions, VLDL, LDL, or HDL, was determined by assaying the amount of spin-labeled proteins by EPR spectroscopy (8). Like the native proteins, apoE3-like protein bound preferentially to HDL (49% vs. 27% to LDL and 31% to VLDL) (Fig. 2B), and apoE4 bound predominantly to VLDL (56% vs. 16% to HDL and 27% to LDL).

ApoE4 undergoes a greater spectral change upon incubation with postprandial plasma

The dipolar interaction between the spin labels at two sites can be qualitatively determined by the amount of spectral broadening. Therefore, we examined the double-spin-labeled apoE4 and apoE3-like proteins after incubation in postprandial plasma (Fig. 2A). The spectra in Fig. 2A are plotted so that each represents the same number of spins. The R61T mutation increased the distance between the domains in the lipid-free protein, resulting in less spectral broadening, as shown previously (10). Postprandial plasma decreased the dipolar broadening of apoE4. The effect was greatest at 3.5 h, but the broadening was less than that in the apoE3-like sample. This suggests that this population of apoE4 retains some of the conformational features of its lipid-free state in plasma. In contrast, the apoE3-like protein maintained a more open conformation both in the lipid-free state and in plasma. This difference allows a systematic investigation of apoE isoform-specific behavior in the postprandial state. Fasting and postprandial serum lipid values of six of the healthy volunteers who participated in this study are listed in Table 1.

Preferential distribution of spin-labeled apoE3-like protein and apoE4 with plasma lipoproteins

To determine if the apoE3-like and apoE4 mutants have binding preferences similar to those of the native proteins, we incubated fasting plasma from healthy volunteers with spin-labeled apoE3-like protein (61T-76C-241C) or apoE4 (76C-241C) for 1 h at 37°C. The samples were separated by agarose gel electrophoresis. The extent of binding and relative distribution of exogenously added apoE3-like protein or apoE4 with plasma lipoprotein fractions, VLDL, LDL, or HDL, was determined by assaying the amount of spin-labeled proteins by EPR spectroscopy (8). Like the native proteins, apoE3-like protein bound preferentially to HDL (49% vs. 27% to LDL and 31% to VLDL) (Fig. 2B), and apoE4 bound predominantly to VLDL (56% vs. 16% to HDL and 27% to LDL).
Lipid fluidity affects structural conformation of apoE4. These data suggest that the conformation of apoE4 is more affected on VLDL than on HDL or LDL. Using synthetic lipids, Hatters et al. (10) found similar apoE4 conformational changes. However, this is the first report to show the differences in apoE4 conformation on native lipoproteins.

Fig. 2. A: Effect of fasting and postprandial plasma (from volunteer 7135) on the EPR spectra of spin-labeled apoE3-like protein and apoE4. apoE3-like or apoE4 were incubated with pre- or postprandial plasma at 37°C for 1 h before scanning. Each spectrum represents the same number of spins from a spin-labeled apoE3 or apoE4 at a concentration of 0.2 mg/ml. B: Distribution of spin-labeled apoE3-like or apoE4 associated with plasma lipoproteins. The protein samples were incubated at 37°C for 1 h with fasting plasma samples from healthy human subjects. The lipoproteins were separated by gel electrophoresis and stained with Fat Red 7b. The VLDL, LDL, and HDL bands were excised and solubilized into 4.5 mol/l guanidine isocyanate by incubating at 65°C for 3 min. The gel extracts were subjected to EPR spectroscopy. Data represent the average of six independent measurements. Error bars represent SD. *P < 0.001 for significantly different treatments within each apoE (E3/E4) protein group. #P < 0.001 for significantly different treatments within each lipoprotein class.

Volunteers 9126 and 2206 were reinvited for the study; therefore, the data from those volunteers are averages of two independent measurements. The data from volunteers 7125, 2654, 2020, and 6341 are from a single experiment. TG, total TGs; TC, total cholesterol; LDL, direct measurement of LDL-cholesterol; HDL, direct measurement of HDL-cholesterol.

an increase of ~30% over the lipid-free protein. However, for apoE4, the increase in the center peak amplitude was much higher for apoE4 bound to VLDL (2.15-fold) than for apoE4 bound to either HDL (1.8-fold) or LDL (1.7-fold). The proximity of the spin labels in the two domains in apoE4 was most similar to that of apoE3 on VLDL-bound apoE4 (Fig. 3). These data suggest that the conformation of apoE4 is more affected on VLDL than on HDL or LDL. Using synthetic lipids, Hatters et al. (10) found similar apoE4 conformational changes. However, this is the first report to show the differences in apoE4 conformation on native lipoproteins.

Lipid fluidity affects structural conformation of apoE4
Dependence of apoE conformation on postprandial HDL and VLDL

To confirm that the decrease in apoE spin interaction after exposure to postprandial plasma can be attributed to the VLDL-associated protein, we incubated apoE4 and apoE3-like proteins with lipoprotein fractions isolated from fasting plasma (P0) or postprandial plasma obtained at 3.5 (P3.5) or 6 h (P6). P6 plasma served as an internal control to P0 plasma. ApoE4 maintained the proximity of the 76 and 241 probes to a larger extent on HDL (Fig. 4). In contrast with the effect seen when combined with the mixture of lipoproteins in plasma (Fig. 2A), postprandial HDL did not influence the conformation of apoE4, as judged by the spectrum of the doubly labeled protein (Fig. 4). Similarly, the conformation of the apoE3-like protein was not altered by incubation with HDL fractions from the fasting (P0) or postprandial states (P3.5 and P6). However, both spin-labeled apoE4 and the apoE3-like proteins displayed significant spectral narrowing after exposure to P3.5 VLDL (Fig. 4).

VLDL lipolysis affects the conformation of apoE

Because increased lipolytic activity is associated with the postprandial state, we examined the effect of VLDL lipolysis on apoE conformation. Equal amounts of spin-labeled apoE3-like protein or apoE4 were incubated with LpL-treated or untreated postprandial VLDL for 1 h at 37°C before scanning. Compared with lipid-free apoE4 in buffer, apoE4 incubated with postprandial VLDL generated a 2.7-fold greater signal intensity, which increased to 3.5-fold when apoE4 was incubated with LpL-treated VLDL (Fig. 4, inset). ApoE3-like protein showed a 1.4-fold increase in signal intensity when treated with VLDL and a 1.8-fold increase when treated with LpL-treated VLDL.

To determine if lipolyzed VLDL has higher affinity for apoE, we used agarose gel electrophoresis to examine apoE4 that had been incubated with VLDL or LpL-treated VLDL. The VLDL bands on the gels were visualized by staining, and the gel slices were solubilized in 4.5 mol/l guanidine isothiocyanate by incubating at 65°C for 3 min. We measured the signal from the samples to determine the amount of exogenously added protein associated with VLDL or LpL-treated VLDL. Lipolysis did not significantly alter the association of VLDL with either apoE4 or apoE3-like protein. Variations in association of apoE4 with VLDL or LpL-treated VLDL were negligible. Therefore, the differences in the EPR signal amplitude reflect changes in apoE4 conformation, not the amount of apoE4 bound to the lipoproteins.

Lipid fluidity of lipoproteins

Next, we used DSA probes to investigate whether differences in lipoprotein particle fluidity influence the struc-
Lipid fluidity affects structural conformation of apoE4

To measure particle fluidity, we added 5-DSA, 12-DSA, or 16-DSA (2 µmol/l) to HDL, LDL, VLDL, or LpL-treated VLDL and subjected the lipoproteins to EPR spectroscopy. The spin labels in each probe showed restricted movement upon equilibration with LDL or HDL but relatively free mobility upon equilibration with VLDL (Fig. 5). Increased mobility of the spin label, indicated by a narrower and sharper spectrum, can be quantified by a decrease in the order parameter S (Table 2). These results show that VLDL is more fluid than LDL and HDL.

Effect of lipolysis on TGRL fluidity

We investigated the role of LpL in the increased fluidity of postprandial lipoproteins. The effect of LpL treatment on the lipid order within VLDL and chylomicrons also was examined using spin-labeled fatty acids (Fig. 6A). Both the 12- and 16-DSA probes displayed clear narrowing of the lines and lowered order parameters (Table 2) with lipolysis treatment, revealing greater mobility, and increased rates of motion, indicating a more fluid environment. Lipolysis had little effect on the 5-DSA probe, suggesting that the headgroup region is less affected by lipolysis.

To investigate the actions of lipolysis on TGRL fluidity, we used fatty acid spin probes (doxyl stearic acid) and a cholesterol spin probe (spin-labeled cholestanol) to study lipid fluidity changes. We incubated TGRL, untreated or treated with LpL, with the spin-labeled cholestanol spin probe (20 µmol/l) and performed EPR spectroscopy to assess the mobility of cholesterol-rich domains. Lipolysis increased the fluidity TGRL (both chylomicrons and VLDL) (Fig. 6B). The influence of decreased TGRL fluidity was also explored by preparing triolein-phosphatidylcholine emulsions of differing cholesterol content, which is expected to reduce lipid fluidity at higher levels. As shown in Fig. 6C, apoE4 displays a slightly higher level of domain interaction when incubated with TGRL mimics containing the higher cholesterol level, while no difference was detected for the apoE3-like sample. In summary, the data with various lipid probes indicate that lipolysis increases the fluidity of lipoproteins, and when added to the previous data, suggest that the proximity of positions in apoE indicative of domain interaction provide a marker of lipolysis activity and thereby lipoprotein fluidity.

Finally, to evaluate the compositional changes in VLDL after lipolysis, we assayed the free fatty acid content of postprandial VLDL (350 mg/dl TG) in the absence of LpL treatment. Lipolysis of VLDL (3 U/ml) increased the levels of NEFAs by 15-fold (from 0.04 to 0.655 mmol/l). Total NEFA

Fig. 4. Postprandial apoE conformation is modulated by VLDL but not HDL. Spectra of apoE4 or apoE3-like protein containing spin labels at positions 76 and 241 in combination with HDL or VLDL fractions isolated from volunteers at either the fasting P(0) or postprandial time points (3.5 and 6 h). Insets: Lipolysis-induced structural changes in apoE-associated with VLDL. The indicated protein was incubated with VLDL or LpL-treated VLDL at 37°C for 1 h before scanning. An incubation of the protein in buffer alone is also shown as reference. All samples contained 0.2 mg/ml apoE.
more extended conformation than when associated with LDL or HDL. Our findings suggest a model for apoE association with lipid particles (Fig. 7). These conformational changes may be important in lipoprotein-vascular cell binding and possibly in vascular injury.

Lipid association induces structural rearrangements in apoE. The conformation of apoE4 differs, depending on whether it is complexed to phospholipid alone or TG-rich emulsions (10). Plasma lipoproteins are highly variable in size and composition, and apoE4 and apoE3 have different preferences for plasma lipoproteins. However, no reports examine these lipoproteins for different effects on apoE conformation. ApoE4 showed different conformations on VLDL versus HDL and LDL, showing a more dramatic effect on VLDL compared with HDL or LDL. ApoE3 conformation was relatively unchanged by association with these different lipoprotein classes. The reason for the apoE4 structural conformational change is not known. Studies with model lipoproteins have shown that molecular packing of lipids and the structures of lipids and apolipoproteins are important determinants of the equilibrium binding and kinetics of transfer of apolipoproteins (23–26). Among lipoproteins, surface lipid fluidity increased in the order HDL < LDL < VLDL and varied inversely with their (protein + cholesterol/phospholipid) ratios (27).

We used the EPR mutant clones of apoE [apoE4 (76C-241C) and apoE3-like protein (R61T, 76C, 241C)] to monitor conformational effects. Like the native apoE proteins, spin-labeled apoE4 preferentially associated with VLDL and apoE3-like protein with HDL after a moderately high-fat meal. Thus, the mutations in these proteins did not affect their structural integrity or their preference for plasma lipids.

Our findings are consistent with earlier work by Massey and Pownall (27), who used fluorescent probes to find a similar fluidity for HDL and LDL but a more fluid environment for VLDL. They showed a positive correlation between surface fluidity of lipoprotein particles with reactivity of phospholipase A2. Gorshkova, Menschikowski, and Jaross (28) showed that phospholipase A2 treatment increases order at the headgroup (as detected by 5-DSA). Thus, the mutations in these proteins did not affect their structural integrity or their preference for plasma lipids.

Our findings are consistent with earlier work by Massey and Pownall (27), who used fluorescent probes to find a similar fluidity for HDL and LDL but a more fluid environment for VLDL. They showed a positive correlation between surface fluidity of lipoprotein particles with reactivity of phospholipase A2. Gorshkova, Menschikowski, and Jaross (28) showed that phospholipase A2 treatment increases order at the headgroup (as detected by 5-DSA). This is consistent with the insignificant change in VLDL fluidity by the 5-DSA probe. Thus, the surface density may be relatively unaffected, while the core becomes much more fluid. Foucher et al. (29) found that PUFAs make lipoproteins more fluid than saturated. Previously, we showed that adding palmitate to VLDL reduced C-terminal (i.e., intermolecular) interaction and promoted the transition of apoE4 from a tetrameric state to a monomeric state.

**DISCUSSION**

In this study, we used EPR spectroscopy to investigate conformational changes of apoE4 induced by VLDL lipolysis products. Our findings show that the conformation of apoE4 is modulated postprandially and is mediated by VLDL particle fluidity. ApoE4 was more sensitive to surface lipid fluidity than apoE3, and lipid fluidity was inversely related to the proximity of regions in the N- and C-terminal domains of apoE4. VLDL was much more fluid than LDL and HDL, and VLDL-associated apoE4 had a more extended conformation than when associated with LDL or HDL. Our findings suggest a model for apoE association with lipid particles (Fig. 7). These conformational changes may be important in lipoprotein-vascular cell binding and possibly in vascular injury.

Lipid association induces structural rearrangements in apoE. The conformation of apoE4 differs, depending on whether it is complexed to phospholipid alone or TG-rich emulsions (10). Plasma lipoproteins are highly variable in size and composition, and apoE4 and apoE3 have different preferences for plasma lipoproteins. However, no reports examine these lipoproteins for different effects on apoE conformation. ApoE4 showed different conformations on VLDL versus HDL and LDL, showing a more dramatic effect on VLDL compared with HDL or LDL. ApoE3 conformation was relatively unchanged by association with these different lipoprotein classes. The reason for the apoE4 structural conformational change is not known. Studies with model lipoproteins have shown that molecular packing of lipids and the structures of lipids and apolipoproteins are important determinants of the equilibrium binding and kinetics of transfer of apolipoproteins (23–26). Among lipoproteins, surface lipid fluidity increased in the order HDL < LDL < VLDL and varied inversely with their (protein + cholesterol/phospholipid) ratios (27).

We used the EPR mutant clones of apoE [apoE4 (76C-241C) and apoE3-like protein (R61T, 76C, 241C)] to monitor conformational effects. Like the native apoE proteins, spin-labeled apoE4 preferentially associated with VLDL and apoE3-like protein with HDL after a moderately high-fat meal. Thus, the mutations in these proteins did not affect their structural integrity or their preference for plasma lipids.

Our findings are consistent with earlier work by Massey and Pownall (27), who used fluorescent probes to find a similar fluidity for HDL and LDL but a more fluid environment for VLDL. They showed a positive correlation between surface fluidity of lipoprotein particles with reactivity of phospholipase A2. Gorshkova, Menschikowski, and Jaross (28) showed that phospholipase A2 treatment increases order at the headgroup (as detected by 5-DSA). This is consistent with the insignificant change in VLDL fluidity by the 5-DSA probe. Thus, the surface density may be relatively unaffected, while the core becomes much more fluid. Foucher et al. (29) found that PUFAs make lipoproteins more fluid than saturated. Previously, we showed that adding palmitate to VLDL reduced C-terminal (i.e., intermolecular) interaction and promoted the transition of apoE4 from a tetrameric state to a monomeric state.
Lipid fluidity affects structural conformation of apoE

The mechanisms are not known with certainty. Our studies indicate that the postprandial state can significantly alter the structural conformation of apoE4. Further research is necessary to determine whether postprandial conformational changes in apoE4 affect its interactions with cells and contribute to atherogenicity. Postprandial hyperlipemia occurs several times daily, and postprandial lipoproteins could injure arterial endothelium and cause repetitive arterial injury (32, 33). Because postprandial hyperlipemia has been implicated in the development of atherosclerosis via repetitive injury to the arterial endothelium (34), understanding the role of the apoE isoforms and their conformation in modulating pro-inflammatory processes may be very important in atherogenesis.

Our study provides direct evidence that apoE assumes different conformations, depending on its association with lipoprotein species. ApoE4 preferentially binds to VLDL, but the reasons for its preference are not known. We showed that apoE4 assumes a more linear conformation on VLDL particles. The increase in free fatty acid content in VLDL due to lipolysis is accompanied by an increase in lipid fluidity, which affects apoE4 conformation (Fig. 7). From these results, we demonstrate that the conformation of apoE4 is influenced by lipoprotein classes and lipid fluidity. More fluid particles may promote the partition of apoE side chains (favoring lipid-protein vs. protein-protein interactions). Such modulations in apoE4 structure due to changes in lipoprotein fluidity, especially during postprandial state, may regulate lipoprotein binding and uptake by cellular receptors. Additional studies are needed to under-

**Fig. 6.** Effect of lipolysis on fluidity of TGRL. **A:** The effect of lipolysis on the EPR spectra of doxyl-labeled stearic acid in VLDL (top three sets) or chylomicrons (bottom set). In each experiment, an equal amount of TGRL sample (200 mg/dl TG) was pretreated with LpL for 30 min to generate lipolysis products prior to addition of the 16-DSA spin label. The arrows in the chylomicron spectrum highlight the increase in the population of highly mobile lipids when the sample is pretreated with LpL (red tracing) as opposed to without LpL pretreatment (black tracing) indicating an increase in lipid fluidity after LpL treatment. **B:** Effect of lipolysis spin-labeled cholesterol was added slowly while stirring the lipoprotein sample at 37°C and incubated for 2 h prior to scanning. **C:** Domain interaction of apoE on synthetic lipid particles containing two different concentrations of cholesterol (9 mg/dl or 24 mg/dl). Particles were prepared from synthetic TG rich emulsions as described in Materials and Methods and then incubated with spin-labeled apoE4 or the E3-like protein for 1 h at 37°C, followed by EPR spectroscopy.
stand the relationship between lipoprotein particle fluidity and its relevance to cardiovascular and neurological disease.

CONCLUSIONS

Our study shows differential structural conformation of apoE4 bound to VLDL versus LDL and HDL. Furthermore, lipolysis products of VLDL significantly affect the conformation of apoE4 during the postprandial state by increasing VLDL fluidity. Future studies will explore whether the change in structural conformation of apoE4 has effects on its binding and internalization of apoE4 by cellular receptors. Such studies will increase our understanding of the relevance of apoE4 structural changes in the postprandial state to initiation and contribute to vascular inflammation and atherosclerotic cardiovascular disease.

The authors thank Danielle Baute and Kit Ng for their careful work. The authors also would like to acknowledge Theresa Tonjes of the Clinical Nutrition Research Unit at the University of California, Davis, for her assistance in the quantification of lipoproteins and lipolysis products. Supplies and facilities for part of this study were provided by the Western Human Nutrition Research Center, Ragel Facility, and the Clinical Nutrition Research Unit at the University of California, Davis.
