ABSTRACT
We revisit the well-studied problem of triangle count estimation in graph streams. Given a graph represented as a stream of \( m \) edges, our aim is to compute a \((1 \pm \epsilon)\)-approximation to the triangle count \( T \), using a small space algorithm. For arbitrary order and a constant number of passes, the space complexity is known to be essentially \( \Theta(\min(m^{3/2}/T, m/\sqrt{T})) \) (McGregor et al., PODS 2016, Bera et al., STACS 2017).

We design a streaming algorithm with space complexity \( \tilde{O}(\min(m^{3/2}/T, m/\sqrt{T})) \), which is significantly smaller than both \( m^{3/2}/T \) and \( m/\sqrt{T} \). We complement our algorithmic result with a nearly matching lower bound of \( \Omega(m/\sqrt{T}) \).

1 INTRODUCTION
Triangle counting is a fundamental algorithmic problem for graph streams. Indeed, the literature on this one problem is so rich, that its study is almost a subfield in and of itself. Since the introduction of this problem by Bar-Yossef et al. [9], there has been two decades of research on streaming algorithms for triangle counting [9, 11, 13, 14, 22, 34, 38, 39, 41, 45–48, 59, 60]. The significance of triangle counting is underscored by the wide variety of fields where it is studied: database theory, theoretical computer science, and data mining. From a practical standpoint, triangle counting is a core analysis task in network science. Given the scale of real-world graphs, this task is considered to be computationally intensive. In database systems, triangle counting is used for query size estimation in database join problems (see [5, 7] for details). These have led to the theoretical and practical study of triangle counting in a variety of computational models: distributed shared-memory, MapReduce, and streaming [4, 8, 18, 20, 42, 51, 52, 54, 56–58].

Despite the plethora of previous work in the streaming setting, the following question has not received much attention. Are there “natural” graph classes that admit more efficient streaming algorithms for triangle counting? This question has a compelling practical motivation. It is well known from network science that massive real-world graphs exhibit special properties. Could graph classes that contain such real-world graphs have “better than worst-case” streaming triangle algorithms?

Motivated by these considerations, we study the problem of streaming triangle counting, parametrized by the graph degeneracy (also called the maximum core number). We defer the formal definition for later, but for now, it suffices to think of degeneracy as a nuanced measure of graph sparsity. The class of constant degeneracy graphs is extremely rich: it contains all planar graphs, all minor-closed families of graphs, and preferential attachment graphs. The degeneracy of real-world graphs is well studied, under the concept of core decompositions. It is widely observed that the degeneracy of real-world graphs is quite small, many orders of magnitude smaller than worst-case upper bounds [24, 35, 36, 55].

In computational models other than streaming, the degeneracy is known to be relevant for triangle counting. From the perspective of running time of exact sequential algorithms, a seminal combinatorial algorithm of Chiba-Nishizeki gives an \( O(m) \) time algorithm for exact triangle counting (\( m \) is the number of edges, and \( \kappa \) is the degeneracy) [18]. Thus, for (say) constant degeneracy, this algorithm beats the best known running time bounds of more sophisticated matrix multiplication based algorithm (of course, the latter work for all graphs) [2]. In distributed and query-based computational models, a number of results have shown that low degeneracy is helpful in bounding communication or query complexities [30, 33, 36, 56]. This inspires the main question addressed by this paper.

Do there exist streaming algorithms for approximate triangle counting on low degeneracy graphs that can beat known worst-case lower bounds?

1.1 Our results and significance
We focus on constant pass streaming algorithms, with arbitrary order. Thus, we think of the input graph \( G = (V, E) \) represented as an arbitrary list of (unrepeated) edges. Our algorithm is allowed to make a constant number of passes over this list, but has limited storage. As is standard, we use \( n \) for the number of vertices, \( m \) for the number of edges, and \( T \) for the number of triangles in \( G \).

We first define the graph degeneracy.

Definition 1.1. The degeneracy of a graph \( G \), denoted \( \kappa(G) \), is defined as \( \max_{G'} \min \{ \text{degree of } G' \} \). In words, it is the largest possible minimum degree of a subgraph of \( G \).
In a low degeneracy graph, all induced subgraphs have low degree vertices. The following procedure that computes the degeneracy is helpful for intuition. Suppose one iteratively removed the minimum degree vertex from $G$ (updating degrees after every removal). For any vertex $v$, consider the "observed" degree at the time of removal. One can prove that the degeneracy is the largest such degree [1]. Thus, even though $G$ could have a large maximum degree, the degeneracy can be small if high degree vertices are typically connected to low degree vertices.

Our main theorem follows.

**Theorem 1.2.** Consider a graph $G$ of degeneracy at most $κ$, that is input as an arbitrary edge stream. There is a streaming algorithm that outputs a $(1 ± ε)$-approximation to $T$, with high probability\(^1\), and has the following properties. It makes constant number of passes over the input stream and uses space $\tilde{O}(n^{3/2}/T)$, poly($\log n, ε^{-3}$).

To understand the significance of the bound $mκ/T$, note that space complexity of streaming triangle counting is known to be $\min(m^{3/2}/T, m/\sqrt{T})$ [11, 46]. Consider $κ = O(1)$, which as mentioned earlier, holds for all graphs in minor-closed families and preferential attachment graphs. In this case, the algorithm of Theorem 1.2 uses space $\tilde{O}(m/T)$. This is significantly smaller than both $m^{3/2}/T$ and $m/\sqrt{T}$. We note that for all graphs, $κ ≤ \sqrt{2m}$, and thus, the space is always $\tilde{O}(m^{3/2}/T)$.

As an illustrative example, consider the wheel graph with $n$ vertices (take a cycle with $n − 1$ vertices, and add a central vertex connected to all other vertices). Note that $m = T = Θ(n)$ and $κ = O(1)$ ($G$ is planar). The space bound given in Theorem 1.2 is only polylogarithmic, while all existing streaming algorithms bounds (given in Table 1) are $Ω(\sqrt{n})$.

Our bound of $\tilde{O}(mκ/T)$ subsumes the term $\tilde{O}(m^{3/2}/T)$, and dominates the term $\tilde{O}(m/\sqrt{T})$ when $T = Ω(k^2)$. For real-world graphs, $T = Ω(k^2)$ is a naturally occurring phenomenon. In fact, real-world large graphs are often characterized by following two properties: (1) low sparsity, and (2) high triangle density [25, 50, 53, 61]. Thus, from a practical standpoint, our bound offers significant improvement over previously known bounds.

We complement Theorem 1.2 with a nearly matching lower bound.

**Theorem 1.3.** Any constant pass randomized streaming algorithm for graphs with $m$ edges, $T$ triangles, and degeneracy at most $κ$, that provides a constant factor approximation to $T$ with probability at least $2/3$, requires storage $Ω(mκ/T)$.

We remark that all our results in this paper can be equivalently stated in terms of *arboricity* as well. The *arboricity* of a graph $G$, denoted as $α$, is the smallest integer $p$ such that the edge set $E(G)$ can be partitioned into $p$ forests. It is asymptotically same as degeneracy: for every graph $α ≤ κ ≤ 2α − 1$.

### 1.2 Main ideas

We give a high-level description of our algorithm and proof. The final algorithm has a number of moving parts, and is based on recent advances in sublinear algorithms for clique counting [26, 29, 30].

The starting point for our algorithm (and indeed, most triangle counting results related to degeneracy) is the classic sequential procedure of Chiba-Nishizeki. For every edge $e = (u, v)$, the size of intersection on neighborhoods of $u$ and $v$ is the number of triangles containing $e$. This intersection can be determined easily in $\min(d(u), d(v))$ operations, by searching for elements of the smaller neighborhood in the larger one. (Here, $d(u)$ denotes the degree of vertex $u$.) For convenience, let us define the degree of edge $e$ to be $d_E := \min(d(u), d(v))$. Thus, we can enumerate all triangles in $\sum_e d_E$ time. The classic bound of Chiba-Nishizeki asserts that $\sum_e d_E = \tilde{O}(mκ)$.

As a warmup, let us get an $O(mκ/T)$ space streaming algorithm, that uses a degree oracle. Define $d_E := \sum_e d_E = O(mκ)$. With the degree oracle, in a single pass, we can sample an edge $e$ proportional to its degree. In the second pass, pick a uniform random neighbor $w$ of the lower degree endpoint of $e$. In the third pass, determine if $e$ and $w$ form a triangle. The probability of finding a triangle is exactly $3T/d_E$. By sampling $O(d_E/T) = O(mκ/T)$ independent random edges in the first pass, we can estimate $T$ with $O(mκ/T)$ space.

The main challenge is in removing the degree oracle. As a first step, can we effectively simulate sampling edges proportional to their degree? We borrow a key idea from recent sublinear algorithms for clique counting. First, we sample a set of uniform random edges, denoted $R$. In a second pass, we compute the degree of all edges in $R$. Now, we can run the algorithm described earlier, except we only sample edges of $R$. Observe that in the last sample, taking expectations over $R$, we do sample edges proportional to their degree from the overall graph. Unfortunately, these samples are all correlated by the choice of $R$. How large should $R$ be to ensure that this simulation leads to the right answer?

An alternate viewpoint is to observe that the above approach can give an accurate estimate to the number of triangles incident to $R$, denoted $t_R$. We require $R$ to be large enough, so that $t_R$ can be used to estimate $T$. Let $t_e$ be the number of triangles incident to $e$. The $\{t_e\}$ values can exhibit large variance, even when $κ = O(1)$. Consider a graph formed by $(n − 2)$ triangles that all share a common edge. The graph is planar, so $κ = O(1)$. But one edge is incident to $(n − 2)$ triangles, and all other edges are incident to a single triangle. Thus, the $\{t_e\}$ values have the largest possible variance, and one cannot estimate $T$ by computing $\sum_{e \in R} t_e$ for a small $R$. Note that, for this example graph, our desired streaming algorithm uses only polylogarithmic space ($T = Θ(m), κ = O(1)$).

Another key idea from sublinear clique counting saves the day: assignment rules. The idea is to assign triangles uniquely to edges, so that the distribution of assigned triangles has low variance. The overall algorithm will estimate the number of triangles assigned to $R$, and not count the number of triangles *incident* to $R$. A natural, though seemingly circular, rule is to assign each triangle to the contained edge that itself participates in the fewest triangles. Using properties of graph degeneracy, it is shown in [30] that the maximum number of assigned triangles to any edge is $O(κ)$ (Technically, this is not true. We have to leave some triangles unassigned.)

This leads to another technical complication. In the overall algorithm, when a triangle incident to an edge is discovered, the algorithm needs to determine if the triangle is actually assigned to the edge. This requires estimating $t_e$ for all edges $e$ in the triangle, a potentially space intensive operation. To perform this estimation

---

\(^1\)We use "high probability" to denote errors less than $1/3$.
in $O(mk/T)$ requires subtle modifications to the assignment procedure. It turns out we can ignore triangles containing edges of high degree, and thus, the above $t_k$ estimation is only required for low degree edges. Furthermore, we only need to determine if $t_k = \Omega(k)$, which allows for smaller storage algorithms.

All in all, by choosing parameters carefully, all steps can be implemented using $(mx/T)\text{poly}(\log n, c^{-1})$ storage.

2 RELATED WORK

The triangle counting problem, a special case of more general subgraph counting problem, has been studied extensively in the streaming setting. We present a summary of the significant prior works in Table 1. The upper bounds stated in the table are for randomized streaming algorithms that provide $(1 \pm \epsilon)$-approximation to the true triangle count with probability at least $2/3$. The $\tilde{O}$ notation hides polynomial dependencies on $1/\epsilon$ and $\log n$. The lower bounds are primarily based on the triangle detection problem — detect whether the input graph is triangle free or it contains at least $T$ many triangles. All the results presented in the table are for the arbitrary order stream.

Jha et al. [37] designed a one pass $\tilde{O}(m/\sqrt{T})$-space algorithm with $\pm W$-additive error approximation, where $W$ is the number of two length paths (also called wedges). Braverman et al. [13] gave a two-pass $\tilde{O}(mT^{1/3})$-space algorithm to detect if the input graph is triangle free or it has at least $T$ many triangles. These results are not directly comparable to our work.

The triangle counting problem has been studied in the context of the adjacency list streaming model as well. This model is also known as the vertex arrival model: all the edges incident on a vertex arrive together. McGregor et al. [46] gave one-pass $\tilde{O}(m/\sqrt{T})$-space and two pass $\tilde{O}(m^{3/2}/T)$-space algorithm for the triangle counting problem in this model. We refer to [46] for other related work in this model.

Bounded degeneracy graph family is an important class of graphs from a practical point of view. Many real-world large graphs, especially from the domain of social networks and web graphs, often exhibit low degeneracy ([12, 24, 35, 36, 55], also Table 2 in [12]). Naturally, designing algorithms that are parameterized by degeneracy has been a theme of many works in the streaming settings; some examples include matching size estimation [6, 23, 32], independent set size approximation [21], graph coloring [12]. In the general RAM model, the relation between degeneracy and subgraph counting problems has been explored in [10, 19, 31].

In the graph query model, where the goal is to design sub-linear time algorithms, Eden et al. [28] studied the triangle counting problem, and more generally the clique counting problem in bounded degeneracy graphs. Although the model is significantly different from the streaming model, we port some key ideas from there; see Section 1.2 for a detailed discussion. The relevance of bounded degeneracy has been further explored in the context of estimating degree moments [27] in this model.

3 NOTATIONS AND PRELIMINARIES

For an integer $k$, we denote the set $\{1, 2, \ldots, k\}$ by $[k]$. Throughout the paper, we denote the input graph as $G = (V, E)$. We assume $G$ has $n$ vertices, $m$ edges and $T$ many triangles. We denote the degree of a vertex $v \in V$ by $d_v$, and its neighborhood by $N(v)$. For an edge $e = \{u, v\}$, we define its neighborhood $N(e)$ to be that of the lower degree end point: $N(e) = N(u)$ if $d_u < d_v$; $N(e) = N(v)$ otherwise. Similarly, we define the degree of an edge: $d_e = \min\{d_u, d_v\}$. For a collection of edges $R$, we define $d_R = \sum_{e \in E} d_e$. In particular, $d_E := \sum_{e \in E} d_e$.

Chiba and Nishizeki [19] proved the following insightful connection between the sum of degrees of the edges in a graph $d_E$ and its degeneracy $\kappa$. \footnote{Note that Chiba and Nishizeki [19] stated their results in terms of arboricity. As $\alpha \leq \kappa$ for each graph $G$ with arboricity $\alpha$, the same result holds with respect to degeneracy $\kappa$.}

**Lemma 3.1** (Lemma 2 in [19]). For a graph $G$ with $m$ edges and degeneracy $\kappa$,

$$d_E = \sum_{e \in E} d_e \leq 2mk.$$ 

As a corollary, we get the following result.

**Corollary 3.2** ( [19]). For a graph $G$ with $m$ edges and degeneracy $\kappa$, the maximum number of triangles in $G$ is at most $2mk$.

We use the notation $\tilde{O}(\cdot)$ to hide polynomial dependencies on $(1/\epsilon)$ and $\log n$ terms, where $\epsilon$ is the error parameter. For designing our algorithms, we focus on the expected space usage. This can be easily converted into a worst-case guarantee by applying Markov inequality — simply abort if the space usage runs beyond $\epsilon$ times the expected space usage, for some constant $\epsilon$. This only increases the error probability by an additive $1/c$ amount.

We use the following variants of the Chernoff bound and Chebyshev inequality for analyzing our algorithms.

**Theorem 3.3** (Chernoff Bound [17]). Let $X_1, X_2, \ldots, X_r$ be mutually independent indicator random variables with expectation $\mu$. Then, for every $\epsilon > 0$ with $0 < \epsilon < 1$, we have

$$\Pr \left[ \frac{1}{r} \sum_{i=1}^{r} X_i - \mu \right] \geq \epsilon \mu \leq 2 \exp \left(-\epsilon^2 \mu r/3\right).$$

**Theorem 3.4** (Chebyshev Inequality [3]). Let $X$ be a random variable with expectation $\mu$ and variance $\text{Var}[X]$. Then, for every $\epsilon > 0$,

$$\Pr \left[ |X - \mu| \geq \epsilon \mu \right] \leq \frac{\text{Var}[X]}{\epsilon^2 \mu^2}.$$
is not possible as we do not know the degree of the edges apriori. However, the model that we consider here is tailor-made for this purpose. It shows the effectiveness of degree-biased edge samples in estimating triangle count and provides motivation for taking up a similar sampling approach in the general streaming model.

We present our basic estimator in algorithm 1. In the full algorithm, we will run multiple instances of this estimator in parallel and report the “median of the mean” [15] as our final estimate.

Algorithm 1 A Triangle Estimator

1: procedure IDEALESTIMATOR(Graph $G = (V, E)$)
2: Pass 1: Sample an edge $e$ with probability $d_e/d_E$.
3: Pass 2: Sample a vertex $w$ from $N(e)$ u.a.r.
4: Pass 3: Check if $(e, w)$ forms a triangle.
5: if $\tau = \{e, w\}$ is a triangle then
6: Call ISASSIGNED($\tau, e$).
7: If returned YES, then set $Y = 1$; else set $Y = 0$.
8: else
9: Set $Y = 0$.
10: Set $X = d_E \cdot Y$.
11: return $X$.

Implementation Details. The degree proportional sampling is achieved by using weighted reservoir sampling [16]. On arrival of the edge $e = \{u, v\}$ in the stream, we make two degree queries to find $d_e$. The method ISASSIGNED is required to ensures that every triangle is uniquely associated with one of its three edges. Other than this, there is no constraints on the implementation of this method. For example, we can associate every triangle to the edge with lowest degree, breaking ties arbitrarily (but consistently). Let $t_e$ denote the number of triangles assigned to the edge $e$. Clearly, $\sum_{e \in E} t_e = T$.

Analysis. First, we show the estimator is unbiased.

$$\mathbb{E}[X] = \sum_{e \in E} \frac{d_e}{d_E} \cdot \mathbb{E}[X|e]$$

$$= \sum_{e \in E} d_e \cdot \mathbb{E}[Y|e]$$

$$= \sum_{e \in E} d_e \cdot \frac{t_e}{d_e} = \sum_{e \in E} t_e = T$$

Now we bound the variance of the estimator.

$$\text{Var}[X] \leq \mathbb{E}[X^2] = \sum_{e \in E} \frac{d_e}{d_E} \cdot \mathbb{E}[X^2|e]$$

$$= \sum_{e \in E} d_e \cdot d_E \cdot \mathbb{E}[Y^2|e]$$

$$= \sum_{e \in E} d_e \cdot d_E \cdot \frac{t_e}{d_e}$$

$$= d_E \cdot \sum_{e \in E} t_e = d_E \cdot T$$

So, running $\tilde{O}(\text{Var}[X]/\mathbb{E}[X^2]) = \tilde{O}(d_E/T) = \tilde{O}(mk/T)$-many estimators independently in parallel suffices for a $(1 \pm \epsilon)$-approximate estimate. Since each copy of the estimator requires constant space, the overall space usage is bounded by $\tilde{O}(mk/T)$.

5 OUR MAIN ALGORITHM

In this section, we present our streaming triangle estimator. As promised, our algorithm does not assume access to a degree oracle. If the model is indeed equipped with a degree oracle, then we
can save a few passes over the stream. Perhaps more importantly, the number of queries to the oracle is upper bounded by the space usage of our algorithm. Our main algorithmic result is the following.

**Theorem 5.1.** Consider a graph $G$ of degeneracy at most $k$, that is input as an arbitrary edge stream. There is a streaming algorithm that outputs a $(1 + \varepsilon)$-approximation to $T$, with high probability$^{3}$, and has the following properties. It makes six passes over the input stream and uses space $O(m/kT) \cdot \text{poly}(\log n, 1/\varepsilon)$. We describe our estimator in Algorithm 2. We set the parameters $\ell$ and $\ell$ later in the analysis. In analyzing our algorithm, the procedure $\text{IsAssigned}$ would play a crucial role. As discussed earlier, $\text{IsAssigned}$ takes as input a triangle and an edge, and outputs whether the triangle is assigned to that edge. We want this procedure to possess four properties: (1) For a given triangle, it is either unassigned or assigned uniquely to one of its three participating edges. (2) almost all the triangles are assigned, (3) For any fixed edge, not too many triangles are assigned to it, and (4) The space complexity of the procedure is bounded by $O(m/kT)$. The first two properties are required to ensure the overall accuracy of the estimator. The third property would be central to bounding the variance of the estimator. The final property will ensure the overall space complexity of our triangle estimator is bounded by $O(m/kT)$.

We analyze our triangle estimator assuming a black-box access to a $\text{IsAssigned}$ procedure that satisfies the above four properties. In the next section, we will take up the task of designing such an assignment procedure in the streaming setting. We make the above discussion rigorous and formal below.

Assume $\tau_e$ denotes the number of triangles assigned to the edge $e$ by the procedure $\text{IsAssigned}$. We use $\tau_{\text{max}}$ to denote the maximum number of triangles that any edge has been assigned to: $\tau_{\text{max}} = \max_{e \in E} \tau_e$. Denote the number of triangles that $\text{IsAssigned}$ assigns to some edge by $T = \sum_{e \in E} \tau_e$. Then, for any positive constant $\varepsilon$ and $\delta$, we define an $(\varepsilon, \delta)$-accurate $\text{IsAssigned}$ procedure below.

**Definition 5.2 (($\varepsilon, \delta$)-accurate $\text{IsAssigned}$).** A procedure $\text{IsAssigned}$ that assigns a triangle to an edge or leaves it unassigned, is $(\varepsilon, \delta)$-accurate if it satisfies the following four properties.

1. **Unique Assignment**: For each triangle, it is either unassigned or uniquely assigned to one of the three participating edges. This implies, $T \leq T$. 
2. **Almost All Assignment**: With probability at least $1 - \delta$, $T \geq (1 - 2\varepsilon)T$.
3. **Bounded Assignment**: With probability at least $1 - \delta$, $\tau_{\text{max}} \leq \kappa/\varepsilon$.
4. **Bounded Space Complexity**: Each call requires $O(m/kT)$ bits of space.

We now analyze our algorithm assuming a black-box access to $(\varepsilon, O(1/n^2))$-accurate $\text{IsAssigned}$. The analysis consists of two parts. First, we show that for a certain settings of $r$ and $\ell$, our final estimate $X$ is indeed a $(1 + \varepsilon)$ approximation to the true triangle count. In the sequel, we bound the space complexity of our algorithm.

---

### Algorithm 2 Estimation of triangle count

1. **procedure** $\text{EstimateTriangle}(\text{Graph } G = (V, E))$
2.

7.  
8.  
9.  
10.  
11.  
12.  
13.  
14.  

We begin with analyzing the quality of the (multi)set of uniform random edges $R$. Collectively through Lemmas 5.3 and 5.5 and definition 5.4, we establish that for a suitable choice of the parameter $r$, the (multi)set $R$ possesses desirable properties with high probability.

**Lemma 5.3.** Let $d_R = \sum_{e \in R} d_e$ and $\tau_R = \sum_{e \in R} \tau_e$. For any constant $\varepsilon > 0$ we have

(1) $\mathbb{E}[d_R] = r \cdot \frac{d_e}{m}$ and $\mathbb{E}[	au_R] = r \cdot \frac{T}{m}$.
(2) $\Pr\left[d_R \leq \mathbb{E}[d_R] \cdot \frac{\log n}{\varepsilon}\right] \geq 1 - \frac{1}{\varepsilon^2}$.
(3) $\Pr\left[|\tau_R - \mathbb{E}[\tau_R]| \leq \varepsilon \mathbb{E}[\tau_R]\right] \geq 1 - \frac{1}{\varepsilon^2} \cdot \frac{m - \tau_{\text{max}}}{m}.

**Proof.** We first compute the expected value of $d_R$ and $\tau_R$. We define two sets of random variables, $Y^d_i$ and $Y^t_i$ for $i \in [r]$ as follows: $Y^d_i = d_e$, and $Y^t_i = \tau_e$. Then, $d_R = \sum_{i=1}^{r} Y^d_i$ and $\tau_R = \sum_{i=1}^{r} Y^t_i$. We have

$$E\left[Y^d_i\right] = \sum_{e \in E} \Pr[e_i = e] \cdot E\left[Y^d_i | e_i = e\right] = \frac{1}{m} \sum_{e \in E} d_e = \frac{d_R}{m}.$$ 

Then, by linearity of expectation, we get $E[d_R] = r \cdot d_e/m$. Analogously, we have $E[\tau_R] = r \cdot T/m$. We now turn our focus on the concentration of $d_R$. This is achieved by a simple application of Markov inequality.

$$\Pr\left[ d_R \geq E\left[d_R\right] \cdot \frac{\log n}{\varepsilon}\right] \leq \frac{\varepsilon}{\log n}.$$
To prove a concentration bound on $\tau_R$, we study the variance of $\tau_R$. By independence, we have
\[
\text{Var}[\tau_R] = \sum_{i=1}^{r} \text{Var}[Y_i^2]
\]
\[
\leq \sum_{i=1}^{r} E[(Y_i^2)^2]
\]
\[
= \sum_{i=1}^{r} \sum_{e \in E} \Pr[\epsilon_i = e] E[(Y_i^2)^2|\epsilon_i = e]
\]
\[
= \frac{r \cdot \sum_{e \in E} \tau_e^2}{m}
\]
\[
\leq \frac{r \cdot \tau_{\text{max}} \sum_{e \in E} \tau_e}{m}
\]
\[
= \frac{r \cdot \tau_{\text{max}} f}{m}.
\]

Then, the item (3) of the lemma follows by an application of Chebyshev inequality (Theorem 3.4).

We next define a collection of edges $R$ as good if the conditions in items (2) and (3) in Lemma 5.3 are satisfied. Formally, we have the following definition.

**Definition 5.4 (A good collection of edges).** We call a fixed collection of edges $R$, $\epsilon$-good if the following two conditions are true.

\[
d_R \leq \frac{\log n}{\epsilon} \cdot |R| \cdot \frac{d_E}{m}
\]
\[
\tau_R \in \left[ \left( 1 - \epsilon \right) \cdot |R| \cdot \frac{f}{m}, \left( 1 + \epsilon \right) \cdot |R| \cdot \frac{f}{m} \right]
\]

**Lemma 5.5** (Setting of $r$ for an $\epsilon$-good $R$). Let $0 < \epsilon < 1/6$ and $\epsilon > 20$ be some constants, and $r = \frac{\epsilon \log n \cdot m \cdot \tau_{\text{max}}}{d_R}$. Then, with probability at least $1 - \frac{1}{6 \log n}$, $R$ is $\epsilon$-good.

**Proof.** The lemma follows by plugging in $r = \frac{\epsilon \log n \cdot m \cdot \tau_{\text{max}}}{d_R}$ in Lemma 5.3 and using the bounds on $c$ and $\epsilon$.

We have established that the random collection of edges $R$ is good with high probability. We now turn our attention to the random variable $Y$, as defined on Line 13 Algorithm 2. Together in Lemmas 5.6 and 5.7 we show that, if $R$ is $\epsilon$-good then for a suitably chosen parameter $\ell$, the random variable $Y$ is well-concentrated around its mean.

**Lemma 5.6.** Let $R$ be a fixed collection of edges, and $Y_R$ denote the value of the random variable $Y$ as defined on Line 13 Algorithm 2 on $R$. Then,

1. $E[Y_R] = \frac{\tau_R}{d_R}$,
2. $\Pr \left[ |Y_R - E[Y_R]| \geq \epsilon E[Y_R] \right] \leq \exp \left( -\ell \cdot \frac{\epsilon^2 \cdot \tau_R}{3 \cdot d_R} \right)$.

Proof. Let $e_i$ be the edge sampled in the $i$-th iteration of the for loop at line 4 in Algorithm 2. Then,

\[
E[Y_i = 1] = \sum_{e \in R} \Pr[\epsilon_i = e] \Pr[Y_i = 1|\epsilon_i = e],
\]
\[
= \sum_{e \in R} \frac{d_e}{d_R} \Pr[Y_i = 1|\epsilon_i = e],
\]
\[
= \sum_{e \in R} \frac{d_e}{d_R} \frac{\tau_e}{d_e}
\]
\[
= \frac{\tau_R}{d_R}.
\]

By linearity of expectation, we have the item (1) of the lemma. For the second item, we apply Chernoff bound (Theorem 3.3).

**Lemma 5.7** (Setting of $\ell$ for concentration of $Y_R$). Let $0 < \epsilon < 1/6$ and $\ell > 20$ be some constants, and $\ell = \frac{\epsilon \log n \cdot m \cdot \tau_{\text{max}}}{d_R}$. Then, with probability at least $1 - \frac{1}{6 \log n}$, $Y_R - E[Y_R] \leq \epsilon E[Y_R]$.

**Proof.** By Lemma 5.5, $R$ is $\epsilon$-good with probability at least $1 - \frac{1}{6 \log n}$, Condition on the event that $R$ is $\epsilon$-good. By definition of a $\epsilon$-good set, $\tau_R$ is tightly concentrated around its mean: $\tau_R \in \left[ (1 - \epsilon) \frac{f}{m}, (1 + \epsilon) \frac{f}{m} \right]$. Then, by item 2. in Lemma 5.6, we have

\[
\Pr \left[ |Y_R - E[Y_R]| \geq \epsilon E[Y_R] \right] \leq \exp \left( -\ell \cdot \frac{\epsilon^2 \cdot \tau_R}{3 \cdot d_R} \right)
\]
\[
\leq \exp \left( -\frac{\epsilon \log n}{3} \cdot \frac{m \cdot \tau_{\text{max}}}{d_R} \right)
\]
\[
= o(1/n^3),
\]
where the last line follows from the concentration of $\tau_R$ for $\epsilon$-good $R$. Removing the condition on $R$, we derive the lemma.

We have now all the ingredients to prove that our final estimate is indeed close to the actual triangle count. The random variable $Y$ is scaled appropriately to ensure that its expectation is close to the true triangle count.

**Lemma 5.8.** Assume $r$ and $\ell$ is set as in Lemma 5.5 and Lemma 5.7 respectively. Then, there exists a small constant $\epsilon'$ such that with probability at least $1 - \frac{1}{\epsilon^2 \log n}$, $Y \in \left[ (1 - \epsilon')T, (1 + \epsilon')T \right]$.

**Proof.** With probability at least $1 - \frac{1}{\epsilon^2 \log n}$, $Y_R$ is closely concentrated around its expected value $\tau_R/d_R$ (by Lemma 5.7). More formally,

\[
Y_R \in \left[ (1 - \epsilon) \frac{\tau_R}{d_R}, (1 + \epsilon) \frac{\tau_R}{d_R} \right].
\]

Then, with high probability

\[
X_R \in \left[ (1 - \epsilon) \cdot \frac{m}{r} \cdot \tau_R, (1 + \epsilon) \cdot \frac{m}{r} \cdot \tau_R \right].
\]
Since $R$ is good, with probability at least $1 - \frac{1}{c \log n}$,

$$t_R \in \left[ (1 - \epsilon) r \cdot \frac{T}{m}, (1 + \epsilon) r \cdot \frac{T}{m} \right]$$

Then, with probability at least $1 - \frac{2}{c \log n}$,

$$X_R \in \left[ (1 - 2\epsilon) T, (1 + 2\epsilon) T \right]$$

Removing the conditioning on $R$, and using the bound on $T$ as given in Definition 5.2, we have

$$X \in \left[ (1 - \epsilon') T, (1 + \epsilon') T \right]$$

with probability at least $1 - \frac{4}{c \log n}$, for suitable chosen parameter $\epsilon'$.

This completes the first part of the analysis. We now focus on the space complexity of Algorithm 2.

**Lemma 5.9 (Space Complexity of Algorithm 2).** Assuming an access to a $(\epsilon, \delta)$-accurate ISASSIGNED method, Algorithm 2 requires $\tilde{O}(mk/T)$ bits of storage in expectation.

**Proof.** Clearly, $O(r + \ell)$ space is sufficient to store the set $R$ and sample $\ell$ many edges from it at Line 4. Recall from Lemmas 5.5 and 5.7 that $r = \tilde{O}(m^{s_{\text{max}}}/T)$ and $\ell = \tilde{O}(md_{\text{max}}/(rT))$, respectively. Using the bound on $T$ and $m_{\text{max}}$ from the definition of $(\epsilon, \delta)$-accurate ISASSIGNED method, we derive that $O(r + \ell)$ is $\tilde{O}(mk/T)$ with high probability.

We now account for the space complexity of the ISASSIGNED method. It is called if the the edge-vertex pair $[e, v]$ forms a triangle (if condition at Line 8). Let $Z_{t}$ be an indicator random variable to denote if ISASSIGNED is called during the $i$-th iteration of the for loop at Line 4. Then,

$$\Pr[Z_t = 1|R] = \sum_{e \in E} \frac{d_e}{d_R} \frac{t_e}{d_e} = \frac{t_R}{d_R}.$$ 

Then, the expected number of calls to ISASSIGNED is bounded by $\ell \cdot \frac{t_R}{d_R} = \tilde{O}(\frac{m \log n}{T} \ell)$. Note that $t_R$ can be much different from $t_R$, as it counts the exact number of triangles per edge. However, we show that with constant probability, $t_R$ is at most $\tilde{O}(rT/m)$, which bounds the expected number of calls by $O(1)$. Since each call to ISASSIGNED takes $\tilde{O}(mk/T)$ bits of space, the lemma follows. We now bound $t_R$.

$$E(t_R) = r \sum_{e \in E} \frac{t_e}{m} \cdot \frac{3rT}{m}$$

, where the last equality follows from the fact that $\sum_{e \in E} t_e = 3T$. An application of Markov inequality bounds the probability that $t_R$ is more than $\frac{3rT}{m}$ by a small constant probability, for any large constant $c > 10$.

Thus, assuming an access to a $(\epsilon, o(1/n^2))$-accurate ISASSIGNED method, Lemmas 5.8 and 5.9 together prove our main result in Theorem 5.11.

### 5.1 Assigning triangles to edges

In this section we give an algorithm for the ISASSIGNED procedure in Algorithm 3. Recall from the previous section that we require ISASSIGNED to be $(\epsilon, \delta)$-accurate (see Definition 5.2).

The broad idea is to assign a triangle to the edge with smallest $t_e$. Recall that $t_e$ is the number of triangles that the edge $e$ participates in. However, computing $t_e$ might be too expensive in terms of space required for certain edges. As evident from the analysis of Algorithm 2, we have a budget of $\tilde{O}(mk/T)$ in terms of bits of storage for each call to ISASSIGNED. In this regard, we define "heavy" and "costly" edges and it naturally leads to a notion of "heavy" and "costly" triangles. If a triangle is either "heavy" or "costly", then we do not attempt to assign it to any of its edges. Crucially, we show that the total number of "heavy" and "costly" triangles are only a tiny fraction of the total number of triangles in the graph.

We need to ensure that for any edge $e$, not too many triangles are assigned to $e$ by ISASSIGNED. We achieve this by simply disregarding any edge with large $t_e$ from consideration while assigning a triangle to an edge. Formally we capture this by defining heavy edges and triangles.

**Definition 5.10 ($\epsilon$-heavy edge and $\epsilon$-heavy triangle).** An edge is defined $\epsilon$-heavy if $t_e > \epsilon/k$. A triangle is deemed $\epsilon$-heavy if all the three of its edges are $\epsilon$-heavy.

If the ratio $t_e/\delta_e$ is quite small for an edge $e$, then we need too many samples from the neighborhood $N(e)$ to estimate $t_e$. Roughly speaking, $O(\delta_e/t_e)$ many samples are required for an accurate estimation. In this regard, we define costly edges and costly triangles as follows.

**Definition 5.11 ($\epsilon$-costly edge and $\epsilon$-costly triangle).** An edge $e$ is defined $\epsilon$-costly if $\delta_e/t_e > \epsilon/k$. A triangle is deemed $\epsilon$-costly if any of its three edges is $\epsilon$-costly.

We first show that the number heavy triangles and costly triangles are only a small fraction of the all triangles. Formally, we prove the following lemma.

**Lemma 5.12.** The number of $\epsilon$-heavy triangles and $\epsilon$-costly triangles are bounded by $2\epsilon T$ and $\epsilon T$ respectively.

**Proof.** We begin the proof by first showing that the number of costly triangles is bounded. To prove this, observe that for a costly edge $e$, $t_e < \delta_e \cdot (\epsilon T/mk)$. Then,

$$\sum_{e \text{ is costly}} t_e < \frac{\epsilon T}{mk} \sum_{e \text{ is costly}} \delta_e < \frac{\epsilon T}{mk} \cdot d_E = 2\epsilon T$$

, where the last inequality follows from lemma 3.1.

We now turn our attention to bounding the number of heavy triangles. By a simple counting argument, the number of heavy edges in $G$ is at most $\epsilon T/k$. Consider the subgraph of $G$ induced by the set of heavy edges, denoted as $G_{\text{heavy}}$. It follows from the definition of degeneracy that $\kappa_{\text{G_{heavy}}} \leq \kappa_G$. By Corollary 3.2, the number of triangles in $G_{\text{heavy}}$ is then at most $\kappa_{G_{\text{heavy}}} \cdot E(G_{\text{heavy}}) = \epsilon T$. Since any heavy triangle in $G$ is present in $G_{\text{heavy}}$, the lemma follows.
at Line 7. Given a triangle $\tau$, ASSIGNMENT either returns $\perp$ ($\tau$ is not assigned to any edges) or returns an edge $e$. We remark here that the method ASSIGNMENT as described is randomized and may return different $e$ on different invocations. To ensure that every triangle is assigned to an unique edge, as demanded in the item (1) of Definition 5.2, we maintain a table of (key, value) pairs that maps triangles (key) to edges or $\perp$, symbol(value). In particular, when ASSIGNMENT is invoked with input $\tau$, we first look up in the table to check if there is an entry for the triangle $\tau$. If it is there, then we simply return the corresponding value from the table. Otherwise, we execute ASSIGNMENT with input $\tau$, create an entry for $\tau$ and and store the return value together with $\tau$ in the table. Since the expected number of calls to the ISASSIGNED routine is bounded by $O(1)$ (by Lemma 5.9), this only adds a constant space overhead.

Algorithm 3 Detecting Edge-Triangle Association

1: procedure ISASSIGNED(triangle $\tau = \{e_1, e_2, e_3\}$, edge $e$)
2: Let $e_{\text{min}} = \text{ASSIGNMENT}(\tau)$
3: if $e_{\text{min}} = \perp$ or $e_{\text{min}} \neq e$ then
4: return NO.
5: else
6: return YES.
7: procedure ASSIGNMENT(triangle $\tau = \{e_1, e_2, e_3\}$)
8: for each edge $e \in \tau$ do
9: if $d_e > \frac{m_e^2}{e^2 T}$ then
10: $Y_e = \infty$
11: else
12: for $j = 1$ to 3 do
13: sample $w$ from $N(e)$ u.a.r.
14: if $\{e, w\}$ forms a triangle, set $Y_j = 1$;
15: else set $Y_j = 0$.
16: Let $Y_e = \frac{d_e}{\epsilon T} \sum_{j=1}^{3} Y_j$.
17: Let $e_{\text{min}} = \arg\min_e Y_e$.
18: if $Y_{e_{\text{min}}} > \kappa/(2e)$ then
19: return $\perp$.
20: else
21: return $e_{\text{min}}$.

We next analyze Algorithm 3. The following theorem captures the theoretical guarantees of ISASSIGNED procedure.

**Theorem 5.13.** Let $\epsilon > 0$ and $c > 60$ be some positive constants and $s = \frac{c \log n}{\epsilon} m_e$. Then, Algorithm 3 leads to an $O(1/n^2)$-accurate ISASSIGNED procedure.

In the remaining part of this section, we prove the above theorem. We have already discussed how to ensure ISASSIGNED satisfies item (1) in Definition 5.2. We next take up item (3). We show that not too many triangles are assigned to any fixed edge. In particular, we show that if an edge is “heavy”, then with high probability no triangles are assigned to it. In other words, if an edge $e$ is assigned a triangle by ASSIGNED, then with high probability $t_e \leq \kappa/\epsilon$. It follows then, that for any edge $e$, the number of triangles that are assigned to $e$, denoted as $\tau_e$, is at most $\kappa/\epsilon$ with high probability.

**Lemma 5.14.** Let $e$ be an $\epsilon$-heavy edge. Then with probability at least $1 - \frac{1}{n^2}$, no triangles are assigned to $e$.

**Proof.** First assume $e$ is not an $\epsilon$-costly edge. Let $\tau$ be some triangle that $e$ participates in. We consider an execution of ASSIGNMENT on input $\tau$. Clearly, $\Pr[Y_e = 1] = t_e/d_e$. By linearity of expectation, $\mathbb{E}[Y_e] = t_e$. An application of Chernoff bound (Theorem 3.3) yields

$$\Pr[Y_e < \kappa/(2e)] \leq \Pr[Y_e < t_e/2] \leq \exp\left(-\frac{1}{12} \frac{s d_e}{t_e}\right) \leq \exp\left(-\frac{c \log n}{\epsilon^2} \frac{st_e}{d_e}\right) \leq \frac{1}{n^2}$$

where the last inequality uses the fact that $e$ is not $\epsilon$-costly and hence $d_e/t_e \leq \max(\epsilon/\epsilon' T)$. Next assume $e$ is an $\epsilon$-costly edge. Since $t_e > \kappa/\epsilon$, it follows that $d_e > \frac{m_e^2}{\epsilon^2 T}$. Then, the condition on Line 9 is true and hence $Y_e = \infty$. So no triangles that $e$ participates in, will be assigned to it.

We now consider item (2) in Definition 5.2. Let $\tau$ be a triangle such that $\tau$ is neither $\epsilon$-heavy nor $\epsilon$-costly. We prove that with high probability, ASSIGNED does not return $\perp$ when invoked with $\tau$. By Lemma 5.12, this implies that $T \geq (1 - 3\epsilon/2)T$.

**Lemma 5.15.** Let $\tau$ be a triangle that is neither $4\epsilon$-heavy nor $4\epsilon$-costly. Then with probability at least $1 - o(1/n^2)$, $\text{ASSIGNED}(\tau) \neq \perp$.

**Proof.** Since $\tau$ is not $4\epsilon$-heavy, for each edge $e \in \tau$, $t_e \leq \kappa/(4\epsilon)$. Since $\tau$ is not $4\epsilon$-costly, at least one edge is not $4\epsilon$-costly — let $e$ denote that edge. Then, $d_e/t_e \leq \max(\epsilon/4\epsilon T)$. Together, they imply $d_e \leq \max^2/(16\epsilon^2 T)$, and the if condition on Line 8 is not met. We next show that, with high probability $Y_e < \kappa/(2e)$. By linearity of expectation, $\mathbb{E}[Y_e] = t_e$. An application of Chernoff bound (Theorem 3.3), similar to the previous lemma, shows that with probability at least $1 - \frac{1}{n^2}$, $Y_e \leq 2t_e \leq \kappa/(2e)$. Hence, with high probability, the triangle $\tau$ is assigned to the edge $e$, proving the lemma.

We now have all the necessary ingredients to complete the proof of the theorem.

**Proof of Theorem 5.13.** We have already argued how to ensure that ISASSIGNED procedure satisfies item (1) in Definition 5.2. Lemmas 5.14 and 5.15 proves that ISASSIGNED satisfies item (2) and item (3) of Definition 5.2. Finally, the space bound in item (4) is enforced by the setting of the parameter $s$.

**6 LOWER BOUND**

In this section we prove a multi-pass space lower bound for the triangle counting problem. Our lower bound, stated below, is effectively optimal.

**Theorem 6.1.** Any constant pass randomized streaming algorithm for graphs with $m$ edges, $T$ triangles, and degeneracy at most $\kappa$, that provides a constant factor approximation to $T$ with probability at least $2/3$, requires storage $\Omega(m\kappa/\epsilon T)$. 
Our proof strategy follows along the expected line of reduction from a suitable communication complexity problem. We reduce from the much-studied \textsc{set-disjointness} problem in communication complexity. It is perhaps a canonical problem that has been used extensively to prove multi-pass lower bounds for various problems, including triangle counting \cite{11,13}. We consider the following promise version of this problem. Alice and Bob have two $N$-bit binary strings $x$ and $y$ respectively, each with exactly $R$ ones. They want to decide whether there exists an index $i \in [N]$ such that $x_i = 1 = y_i$. We denote this as the \textsc{disj}$_N^R$ problem.

The basis of the reduction is the following lower bound for the \textsc{disj}$_N^R$ problem. Assume $E(\textsc{disj}^N_R)$ denote the randomized communication complexity for the \textsc{disj}$_N^R$ problem. \footnote{See \cite{43} for the definition of the notion randomized communication complexity.}

**Theorem 6.2 (Based on \cite{40,49}).** For all $R \leq N/2$, we have $E(\textsc{disj}^N_R) = \Theta(R)$.

To prove our lower bound, we reduce the \textsc{disj}$_N^R$ problem to the following \textsc{triangle-detection} problem. Consider two graph families $G_1$ and $G_2$: $G_1$ is a collection of triangle-free graphs on $n$ vertices and $m$ edges with degeneracy $\kappa$, and $G_2$ consists of graphs on same number of vertices and edges, and with degeneracy $\Theta(\kappa)$ and has at least $T$ many triangles. Given a graph $G \in G_1 \cup G_2$ as a streaming input, the goal of the \textsc{triangle-detection} problem is to decide whether $G \in G_1$ or $G \in G_2$ with probability at least 2/3, making a constant number of passes over the input stream. A lower bound for the \textsc{triangle-detection} problem immediately gives a lower bound for the triangle counting problem.

To set the context for our lower bound result, it is helpful to compare against prior known lower bounds. The multi-pass space complexity of the triangle counting problem is $\Theta(\min(m^{3/2}/T, m/\sqrt{T}))$ \cite{11,22,46} for graphs with $m$ edges and $T$ triangles. We first consider the first term $m^{3/2}/T$. Since $\kappa = O(\sqrt{m})$, our result subsume the bound of $\Theta(m^{3/2}/T)$. Compared between $mk/T$ and $m/\sqrt{T}$, the former is smaller when $T > \kappa^2$. Necessarily, in our lower bound proofs, we will be dealing with graph instances such that $T > \kappa^2$.

For the purpose of proving a $\tilde{\Omega}(mk/T)$ lower bound, it is sufficient to show that the \textsc{triangle-detection} problem requires $\tilde{\Omega}(mk/T)$ bits of space for some specific choice of parameters. However, we cover the entire possible range of spectrum. Fix two parameters $\kappa$ and $r$, such that $r \geq 2$. Then, we can construct an instance of the \textsc{triangle-detection} problem with degeneracy $\Theta(\kappa)$ and $T = \kappa^r$ such that solving it requires $\tilde{\Omega}(mk/T)$ bits of space. So in effect, we prove a more nuanced and arguably more general theorem than the one give in Theorem 6.1. Formally, we show the following.

**Theorem 6.3.** Let $\kappa$ and $r$ be parameters such that $r \geq 2$. Then there is a family of instances with degeneracy $\Theta(\kappa)$ and $T = \kappa^r$ such that solving the \textsc{triangle-detection} problem requires $\tilde{\Omega}(mk/T)$ bits of space.

**Proof.** We reduce from the \textsc{disj}$_{N/3}$ problem. Let $(x, y)$ be the input instance for this problem. We then construct an input $G$ for the \textsc{triangle-detection} problem such that if $(x, y)$ is a YES instance, then $G \in G_1$, and otherwise $G \in G_2$. The graph $G$ has a fixed part and a variable part that depends on $x$ and $y$. We next describe the construction of the graph $G$.

Let $G_{\text{fixed}} = (A \cup B, E_{\text{fixed}})$ be a complete bipartite graph on the bi-partition $A$ and $B$. Then, $E_{\text{fixed}} = \{(a, b) \mid a \in A, b \in B\}$. Further assume $|A| = |B| = p$. We add $N$ blocks of vertices to $G_{\text{fixed}}$ and denote them as $V_1, V_2, \ldots, V_N$. Assume $|V_i| = q$ for each $i \in [N]$. We will set the parameters $p$ and $q$ later in the analysis. For each index $i \in [N]$ such that $x_i = 1$, Alice connects each vertex in $V_i$ to each vertex in $A$. Denote this edge set as $E_A$. For each index $i \in [N]$ such that $y_i = 1$, Bob connects each vertex in $V_i$ to each vertex in $B$. Denote this edge set as $E_B$. This completes the construction of the graph $G$. To summarize, $G = (V, E)$ where $V = A \cup B \cup V_1 \cup \ldots \cup V_N$, and $E = E_{\text{fixed}} \cup E_A \cup E_B$.

It is easy to see that the graph $G$ is triangle-free if and only if there does not exits any $i \in [N]$ such that $x_i = 1 = y_i$. We now analyze various parameters of $G$. In both YES and NO case for the \textsc{disj}$_{N/3}$ problem, we have

$$n = |V| = 2p + Nq$$
$$m = |E| = p^2 + 2 \cdot \frac{N}{3} pq .$$

In the NO instance, the number of triangles $T$ is at least $p^2 q$. As argued above, in the YES instance, $T = 0$. Finally, we compute the degeneracy $\kappa$ in both the cases. Note that $\kappa(G_{\text{fixed}}) = p$, and by definition (see Definition 1.1) $\kappa(G) \geq p$. We claim that $\kappa = p$ in the YES instance and $\kappa \leq 2p$ in the NO instance. To prove the claim, we use the following characterization of degeneracy. Let $< be a total ordering of the vertices and let $d^G_v$ denote the number of neighbors of $v$ that appears after $v$ according to the ordering $<$. Let $d^G_{\max} = \max_{v \in V} d^G_v$. Then, $\kappa \leq d^G_{\max}$. Now consider the following ordering: $V_1 < V_2 < \ldots < V_N < A < B$, and inside each set the vertices are ordered arbitrarily. Then, in the YES instance, $d^G_{\max} = p$ and in the NO instance $d^G_{\max} \leq 2p$, proving our claim.

We now set the parameters $p$ and $q$ as $p = \kappa$ and $q = \kappa^{r-2}$. Then, $m = \Theta(Npq)$ since $p = O(Nq)$. Assume there is a constant pass $\sigma(mk/T)$-space streaming algorithm $A$ for the \textsc{triangle-detection} problem. Then, following standard reduction, $A$ can be used to solve the \textsc{disj}$_{N/3}$ problem with $\sigma(Npq \cdot p/p^2 q) = o(N)$ bits of communication, contradicting the lower bound for the \textsc{disj}$_{N/3}$ problem.

\hfill $\Box$

\section{Future Directions}

In this paper, we studied the streaming complexity of the triangle counting problem in bounded degeneracy graphs. As we emphasized in the introduction, low degeneracy is an often observed characteristics of real-world graphs. Designing streaming algorithms with better bounds on such graphs (compared to the worst case) is an important research direction. There have been some recent successes in this context — graph coloring \cite{12}, matching size estimation \cite{6,23,32}, independent set size approximation \cite{21}. It would be interesting to explore what other problems can admit better streaming algorithms in bounded degeneracy graphs. One natural candidate is the arbitrary fixed size subgraph counting problem, which asks for the number of occurrences of the subgraph in the given input graph.
Do there exist streaming algorithms for approximate subgraph counting on low degeneracy graphs that can beat known worst-case lower bounds?

We conclude this exposition with the following conjecture about the fixed size clique-counting problem.

**Conjecture 7.1.** Consider a graph \( G \) with degeneracy \( \kappa \) that has \( T \) many \( \epsilon \)-cliques. There exists a constant pass streaming algorithm that outputs a \((1 + \epsilon)\)-approximation to \( T \) using \( \tilde{O}(m^{1-2/(2T)}) \) bits of space.
