(Dated: January 20, 2004)

We investigate the space of quantum operations, as well as the larger space of maps which are positive, but not completely positive. A constructive criterion for decomposability is presented. A certain class of unistochastic operations, determined by unitary matrices of extended dimensionality, is defined and analyzed. Using the concept of the dynamical matrix and the Jamiołkowski isomorphism we explore the relation between the set of quantum operations (dynamics) and the set of density matrices acting on an extended Hilbert space (kinematics). An analogous relation is established between the classical maps and an extended space of the discrete probability distributions.

I. INTRODUCTION

The theory of quantum information has been studied for at least forty years – consult e.g. some early papers by Ingarden and his group written in sixties and seventies $^{43, 44, 46, 55}$. However, rapid progress of this theory occurred only in the last decade $^{5, 13, 43, 50, 74}$ due to a synergetic feedback with several recent experiments on quantum physics, motivated by information encoding and processing. The possibility to encode the information in quantum states triggered an increasing interest in the structure and the properties of the set of quantum states $^{10, 13, 47, 52, 69}$. Usually one considers states acting on a finite dimensional Hilbert space, $\mathcal{H}_N$.

To characterize the way that information is processed according to the laws of quantum mechanics, one needs to describe the dynamics of the density matrices. In many cases it is sufficient to consider discrete dynamics, which maps an initial state $\rho$ into the final state $\rho'$. Such maps are often called quantum channels, and their theory is a subject of considerable recent interest $^{5, 13, 43, 74}$.

The set of quantum states $\mathcal{M}^{(N)}$ consists of density matrices of size $N$, which are normalized, hermitian, and positive definite. A quantum channel is called positive, if it maps the set of positive operators into itself. However, since a physical system under consideration may be coupled with an environment, the maps describing physical processes should be completely positive (CP), which means that all their extensions into higher dimensional spaces remain positive. Any CP map may be (not uniquely) represented in the so-called Kraus form, by a collection of Kraus operators $^{60}$.

Even though positive, but not completely positive, maps cannot be realized in the laboratory, they are of a great theoretical importance, since they can be used to detect entanglement in density matrices written on paper $^{57, 11}$. The phenomenon of quantum entanglement seems to be crucial in the theory of quantum information. The structure of the set of all completely positive maps, $\mathcal{CP}_N$, is relatively well understood $^{10}$, but the task to characterize the larger set of all positive maps is far from being completed $^{61, 71, 97}$.

The aim of this work is twofold. On one hand we present a concise review of recent development concerning the properties of the set of quantum maps. On the other hand, we present several new results in this field. In particular, in section 2 concerning the matrix algebra, we define a simple transformation of a matrix, called reshuffling, and establish a useful lemma: The Schmidt coefficients of a matrix $A$, treated as an element of a composite Hilbert-Schmidt space of operators, are equal to the squared singular values of the reshuffled matrix $A^R$. In section 3 we investigate the properties of the dynamical matrix $D$ associated with any linear map $^{94}$ - it may be obtained by reshuffling of the superoperator $L$ which describes the map. Furthermore, we define a class of unistochastic maps, which are determined by a single unitary matrix $U$ of size $N^2$.

For any CP map the corresponding dynamical matrix $D$ is hermitian and positive definite. Making use of the eigen representation of $D$ one may define the canonical Kraus form of the operation. In section 5 we present a comparison between different classes of quantum maps, acting on the space of density matrices, with the classes of classical maps acting on the simplex $\Delta_{N-1}$ of discrete, $N$-point probability measures. For concreteness we present in section 6 certain exemplary maps acting in the space of qubits - the density matrices of size $N=2$.

In section 7 the positive, co-positive and decomposable maps are analyzed and a constructive criterion for decomposability of a map is provided. Furthermore, for any quantum map we introduce three quantities useful to locate...
it with respect to the boundaries of the sets of positive (CP, CcP) maps. In the subsequent sections we explore the Jamiołkowski isomorphism \(\mathcal{HS}\), which relates the set of quantum maps acting on \(\mathcal{M}(N)\), with the states from \(\mathcal{M}(N^2)\), which act on the extended Hilbert space \(\mathcal{H}_N \otimes \mathcal{H}_N\). This isomorphism, formulated as well in the quantum, as well as in the classical setup, allows us to discover an analogy between objects, sets and problems concerning quantum maps and quantum states. This key issue of the work explains its title: there exists a kind of duality between properties of the set of quantum maps (dynamics) and the the set quantum states of a composite \(N \times N\) system (kinematics).

II. ALGEBRAIC DETOUR: MATRIX RESHAPING AND RESHUFFLING

In this section we are going to discuss some simple algebraic transformations performed on complex matrices, which prove useful in description of quantum maps. In particular, we introduce a convenient notation to work in the composite Hilbert space \(\mathcal{H}_N \otimes \mathcal{H}_M\) or in the Hilbert–Schmidt (HS) space of linear operators, \(\mathcal{H}_{\mathcal{HS}}\).

Consider a rectangular matrix \(A_{ij}, i = 1, \ldots, M\) and \(j = 1, \ldots, N\). The matrix may be reshaped, by putting its elements row after row in lexicographical order into a vector \(\vec{a}_k\) of size \(MN\),

\[
\vec{a}_k = A_{ij} \quad \text{where} \quad k = (i - 1)N + j, \quad i = 1, \ldots, M, \quad j = 1, \ldots, N.
\]

(2.1)

Conversely, any vector of length \(MN\) may be reshaped into a rectangular matrix. The simplest example of such a vectorial notation of matrices reads

\[
A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \quad \rightarrow \quad \vec{a} = \{A_{11}, A_{12}, A_{21}, A_{22}\}.
\]

(2.2)

The scalar product between any two elements of the HS space \(\mathcal{H}_{\mathcal{HS}}\) (matrices of size \(N\)) may be rewritten as an ordinary scalar product between two corresponding vectors of size \(N^2\),

\[
\langle A|B \rangle \equiv \text{Tr} A^\dagger B = \vec{a}^\star \cdot \vec{b} = \langle \vec{a}|\vec{b} \rangle.
\]

(2.3)

Thus the HS norm of a matrix is equal to the norm of the associated vector, \(||A||_{\mathcal{HS}} = ||\vec{a}||^2\).

Sometimes we will use both indices and label a component of \(\vec{a}\) by \(a_{ij}\). This vector of length \(MN\) may be linearly transformed into \(a' = Ca\) by a matrix \(C\) of size \(MN \times MN\). Its elements may be denoted by \(C_{k,k'}\) with \(k, k' = 1, \ldots, MN\), but it is also convenient to use a four index notation, \(C_{\mu\nu}^{mn}\), where \(m, n = 1, \ldots, N\) while \(\mu, \nu = 1, \ldots, M\).

In notation the elements of the transposed matrix are \(C_{\mu\nu}^{T} = C_{\mu\nu}^{mn}\), since the upper pair of indices determines the row of the matrix \(C\), while the lower pair determines its column. The matrix \(C\) may represent an operator acting in a composite space \(\mathcal{H} = \mathcal{H}_N \otimes \mathcal{H}_M\). The tensor product of any two bases in both subspaces provides a basis in \(\mathcal{H}\), so that

\[
C_{\mu\nu}^{mn} = \langle e_m \otimes f_\mu|C|e_n \otimes f_\nu \rangle,
\]

(2.4)

where the Roman indices refer to variables of the first subsystem, \(\mathcal{H}_A = \mathcal{H}_N\), and the Greek indices to the second, \(\mathcal{H}_B = \mathcal{H}_M\). The trace of a matrix reads \(\text{Tr} C = C_{\mu\mu}^{mn}\), where summation over the repeating indices is assumed. The operation of partial trace over the second subsystem produces the matrix \(C^A \equiv \text{Tr}_B C\) of size \(N\), while tracing over the first subsystem leads to a \(M \times M\) matrix \(C^B \equiv \text{Tr}_A C\),

\[
C_{\mu\nu}^{A} = C_{\mu\nu}^{mn}, \quad \text{and} \quad C_{\mu\nu}^{B} = C_{\mu\nu}^{mn}.
\]

(2.5)

If \(C\) is a tensor product, \(C = A \otimes B\), then \(C_{\mu\nu}^{mn} = A_{\mu\nu} B_{\mu\nu}\).

Consider a unitary matrix \(U\) of size \(N^2\). Its \(N^2\) columns (rows) \(\vec{u}_k, k = 1, \ldots, N^2\) reshaped into square matrices \(U_k\) of size \(N\) form an orthogonal basis in \(\mathcal{H}_{\mathcal{HS}}\). Using the Hilbert–Schmidt norm, \(||A||_{\mathcal{HS}} = (\text{Tr} A^A)^{1/2}\), we normalize them according to \(A_k = U_k/||U_k||_{\mathcal{HS}}\) and obtain the orthonormal basis, \(\langle A_k|A_j \rangle \equiv \text{Tr} A_k^A A_j = \delta_{kj}\). Alternatively, in a double index notation with \(k = (m-1)N + \mu\) and \(j = (n-1)N + \nu\) this orthogonality relation reads \(\langle A^{\mu\nu}|A^{\nu\nu} \rangle = \delta_{\mu\nu}\).

Note that in general the matrices \(A_k\) (also denoted by \(A^{\mu\nu}\)) are not unitary.

Let \(X\) denote an arbitrary matrix of size \(N^2\). It may be represented as a double (quadruple) sum,

\[
|X\rangle = \sum_{k=1}^{N^2} \sum_{j=1}^{N^2} C_{kj} |A_k \rangle \otimes |A_j \rangle = C_{\mu\nu}^{mn} |A^{\mu\nu} \rangle \otimes |A^{\nu\nu} \rangle
\]

(2.6)
TABLE I: Reorderings of a matrix $X$ representing an operator which acts on a composed Hilbert space. The arrows denote the indices exchanged.

| Transformation | definition $X^T_{mn} = X_{nm}$ | symbol $\updownarrow$ | preserves Hermicity yes | preserves spectrum yes |
|----------------|---------------------------------|----------------------|-------------------------|------------------------|
| flip           | $X^F_{mn} = X_{am} \leftrightarrow$ | $\leftrightarrow$ | yes                      | yes                     |
| partial        | $X^T_{mn} = X_{m b}$             | $\uparrow$          | yes                      | no                      |
| partial        | $X^T_{mn} = X_{mn}$              | $\downarrow$        | yes                      | no                      |
| reshuffling    | $X^R_{mn} = X_{m a}$             |                      | no                       | no                      |
| reshuffling    | $X^R_{mn} = X_{a n}$             |                      | no                       | no                      |
| partial        | $X^P_{mn} = X_{a mn}$            |                      | no                       | no                      |
| partial        | $X^P_{mn} = X_{m an}$            |                      | no                       | no                      |

where $C_{kj} = \text{Tr}( (A_k \otimes A_j)^\dagger X) \text{ may be neither Hermitian nor normal (which means that } C \text{ and } C^\dagger \text{ need not commute).}$

The matrix $X$ may be considered as a vector in the composite Hilbert-Schmidt space, $\mathcal{H}_{HS} \otimes \mathcal{H}_{HS}$, so applying its Schmidt decomposition \cite{81} we arrive at

$$|X\rangle = \sum_{k=1}^{N^2} \sqrt{\lambda_k} |A_k\rangle \otimes |A_k^\mu\rangle,$$

(2.7)

where $\sqrt{\lambda_k}$ are the singular values of $C$, i.e. the square roots of the non-negative eigenvalues of $CC^\dagger$. The sum of their squares is determined by the norm of the operator, $\sum_{k=1}^{N^2} \lambda_k = \text{Tr}(XX^\dagger) = ||X||^2_{HS}$.

Since the Schmidt coefficients do not depend on the initial basis let us analyze the special case, in which the basis in $\mathcal{H}_{HS}$ is generated by the identity matrix, $U = \mathbb{1}$ of size $N^2$. Then each of the $N^2$ basis matrices of size $N$ consist of only one non-zero element which equals unity, $A_k = A^\mu_{\nu} = |m\rangle\langle \nu|$, where $k = N(m - 1) + \mu$. Their tensor products form an orthonormal basis in $\mathcal{H}_{HS} \otimes \mathcal{H}_{HS}$ and allow to represent an arbitrary matrix $X$ in the form (2.7). In this case the matrix of the coefficients $C$ has a particularly simple form, $C_{m\nu} = \text{Tr}( (A^\mu_{\nu} \otimes A^\mu_{\nu}) X ) = X_{m\nu}$.

This particular reordering of a matrix deserves a name so we shall write $X^R = C(X)$ defining the following procedure of reshuffling of matrices. Using this notion our findings may be summarized in the following lemma:

**Schmidt coefficients of an operator $X$ acting on a bi-partite Hilbert space are equal to the squared singular values of the reshuffled matrix, $X^R$.**

More precisely, the Schmidt decomposition (2.7) of any operator $X$ of size $MN$ may be supplemented by a set of three equations

$$\begin{cases}
\{ \lambda_k \}_{k=1}^{N^2} = \{ \text{SV}(X^R) \}^2 : \text{eigenvalues of } (X^R)^\dagger X^R \\
|A'^\mu\rangle : \text{reshaped eigenvectors of } (X^R)^\dagger X^R \\
|A''\rangle \text{ : reshaped eigenvectors of } X^R(X^R)^\dagger
\end{cases}
$$

(2.8)

where we have assumed that $N \leq M$. The initial basis is transformed by a local unitary transformation $W_a \otimes W_b$, where $W_a$ and $W_b$ are matrices of eigenvectors of matrices $(X^R)^\dagger X^R$ and $X^R(X^R)^\dagger$, respectively. If rank $r$ of $X^R(X^R)^\dagger$ equals one, the operator can be factorized into a product form, $X = X_1 \otimes X_2$, where $X_1 = \text{Tr}_2 X$ and $X_2 = \text{Tr}_1 X$.

In general, one may reshuffle square matrices, if its size $K$ is not prime. The symbol $X^R$ has a unique meaning if a concrete decomposition of the size $K = MN$ is specified. If $M \neq N$ the matrix $X^R$ is a $N^2 \times M^2$ rectangular matrix. Since $(X^R)^R = X$ we see that one may also reshuffle rectangular matrices, provided both dimensions are squares of natural numbers. Similar reorderings of matrices were considered by Hill et al. \cite{30,41} while investigating CP maps and later in \cite{14,46,87,88,89} to analyze separability of mixed quantum states.

To get a better feeling of the reshuffling transformation observe that reshaping each row of an initially square matrix $X$ of size $MN$ according to Eq. (2.7) into a rectangular $M \times N$ submatrix, and placing it according to the
lexicographical order block after block, one produces the reshuffled matrix $X^R$. Let us illustrate this procedure for the simplest case $N = M = 2$, in which any row of the matrix $X$ is reshaped into a $2 \times 2$ matrix

$$C_{kj} = X^R_{kj} = \begin{bmatrix} X_{11} & X_{12} & X_{21} & X_{22} \\ X_{13} & X_{14} & X_{23} & X_{24} \\ X_{31} & X_{32} & X_{41} & X_{42} \\ X_{33} & X_{34} & X_{43} & X_{44} \end{bmatrix}.$$ (2.9)

The operation of reshuffling could be defined in an alternative way, say the reshaping of the matrix $A$ from (2.1) could be performed column after column into a vector $\vec{a}'$. In the four indices notation introduced above (Roman indices running from 1 to $N$ correspond to the first subsystem, Greek indices to the second one), both operations of reshuffling take the form

$$X^R_{mn} = X_{\mu\nu} \quad \text{and} \quad X^R_{\mu\nu} = X_{mn}.$$ (2.10)

However, both reshuffled matrices are equivalent up to a certain permutation of rows and columns and transposition, so the singular values of $X^R$ and $X^R$ are equal. It is easy to see that $(X^R)^R = X$. In the symmetric case with $M = N$, the $N^3$ elements of $X$ do not change their position during the operation of reshuffling (these are typeset **boldface** in (2.10)); while the other $N^2 - N^3$ elements are exchanged. The space of complex matrices with the reshuffling symmetry, $X = X^R$, is thus $2N^4 - 2(N^4 - N^3) = 2N^3$ dimensional.

For comparison we provide analogous formulæ showing the action of partial transposition: with respect to the first subsystem, $T_A \equiv T \otimes 1$ and with respect to the second, $T_B \equiv 1 \otimes T$,

$$X^{T_A}_{mn} = X_{\mu\nu} \quad \text{and} \quad X^{T_B}_{mn} = X_{\mu\nu}.$$ (2.11)

Note that all these operations consist of exchanging a given pair of indices. However, while partial transposition (2.11) preserves Hermicity, the reshuffling (2.10) does not. For convenience we shall define a related transformation of flip among both subsystems, $X^F_{\mu\nu} = X^{\nu\mu}$, the action of which consists in relabeling of certain rows (and columns) of the matrix, so its spectrum remains preserved. Note that for a tensor product $Y = Y \otimes Z$ one has $X^F = Z \otimes Y$. In full analogy to partial transposition we use also two operations of partial flip (see table 1). All the above transformations are involutions, since performed twice they are equal to identity. It is not difficult to find relations between them, e.g. $X^{F_1} = [(X^R)^T]^{R'} = [(X^R)^T]^{F'}$. Since $X^R = [(X^R)^T]^T = [(X^R)^T]^F$, while $X^{T_B} = (X^{T_A})^T$ and $X^{F_1} = (X^{F_2})^F$, thus the spectra and singular values of the reshuffled (partially transposed, partially flipped) matrices do not depend on the way each operation has been performed, i.e. $\text{eig}(X^R) = \text{eig}(X^{R'})$ and $\text{SV}(X^R) = \text{SV}(X^{R'})$, ($\text{eig}(X^{F_1}) = \text{eig}(X^{F_2})$ and $\text{SV}(X^{F_1}) = \text{SV}(X^{F_2})$).

### III. COMPLETELY POSITIVE MAPS

Let $\rho \in M(N)$ be a density operator acting on an $N$-dimensional Hilbert space $\mathcal{H}_N$. What conditions need to be fulfilled by a map $\Phi : M^{(N)} \to M^{(N)}$, so it could represent a physical operation? If the map is linear than the image of a mixed state $\rho$ does not depend on the way, how the state $\rho$ was constructed out of projectors. This is a very important feature, since it allows for a probabilistic interpretation of any mixed state. Furthermore, we assume that the map is trace preserving, $\text{Tr}\rho = \text{Tr}\Phi(\rho)$, which corresponds to the conservation of probability.

Any quantum operation has to be positive – it should map any positive density operator into a positive operator. Strictly speaking the term ‘positive’ refers to positive semidefinite Hermitian operators, which do not have negative eigenvalues. However, this condition occurs not to be sufficient to produce physically realizable transformations. Any quantum state $\rho$ may be extended by an ancilla $\sigma$ into a tensor product acting in a $KN$ dimensional Hilbert space. Hence the evolution of a linear map $\Phi$ may be considered as the evolution of a part $\rho$ of a larger system $\rho \otimes \sigma$. Therefore we should require complete positivity [1, 90], which means that for an arbitrary $K$ dimensional extension

$$\mathcal{H}_N \to \mathcal{H}_N \otimes \mathcal{H}_K$$ the map $\Phi \otimes 1_K$ is positive. (3.1)

If the above requirement holds for any fixed $K$, such a property is called $K$-positivity [22, 60, 00]. Constructing the dynamical matrix we will show in the next section that any $N$–positive map $\Phi$ acting on $M^{(N)}$ is completely positive [18]. The importance of complete positivity in quantum mechanics was emphasized in the seventies by Kraus [50], Lindblad [65], and Accardi [2], and the restriction to CP maps is not trivial: There exist quantum maps which are
positive but not completely positive. A simple and important example consists of transposition $T$ of an operator in a given basis, which for Hermitian operators is equivalent to complex conjugation: if $A = A^\dagger$ then $A^T = \bar{A}$. Although the map $T(\rho) = \rho^T$ preserves the spectrum and therefore is positive, its extension $T_A \equiv T \otimes \mathds{1}$, called partial transposition, is not, as discussed in section VII.

A linear CP-map which preserves the trace is called a quantum operation or quantum channel. Any linear, completely positive map $\Phi$ may be represented by a collection of $k$ Kraus operators $A_i$ in the so-called Kraus form

$$\rho \rightarrow \rho' = \Phi(\rho) = \sum_{i=1}^k A_i \rho A_i^\dagger.$$  

(3.2)

It is also called an operator sum representation of the map $\Phi$ or the Stinespring form, since its existence follows from the Stinespring dilation theorem. If the set of Kraus operators satisfies the completeness relation

$$\sum_{i=1}^k A_i^\dagger A_i = \mathds{1},$$  

(3.3)

the map is trace preserving: for any initial state $\rho$ one has $\text{Tr}(\sum_{i=1}^k A_i^\dagger A_i \rho) = \text{Tr}[\Phi(\rho)] = \text{Tr}\rho = 1$. Thus, the Kraus operators may be considered as measurement operators while any trace preserving CP map may be interpreted as a generalized measurement.

Let us denote the elements of the Kraus operators $A_i$ represented in an orthonormal basis by $A_{mn}^{(i)}$. Define a Kraus matrix $M$ of size $N$ composed of non-negative entries

$$M_{mn} = \sum_{i=1}^k |A_{mn}^{(i)}|^2,$$  

(3.4)

where the Kraus operators are now denoted by $A^{(i)}$. The completeness relation enforces that the sum of elements in each column of $M$ equals to unity, so it is a stochastic matrix. Thus quantum operations are often called stochastic maps.

![Quantum operations](image)

FIG. 1: Quantum operations represented by a) unitary operator $U$ of size $NK$ in an enlarged system including the environment, b) black box picture, in which $U$ couples the principal $N$-dimensional system $\rho$ with the environment $\sigma$ of dimensionality $K$.

Any map written in the Kraus form is linear and preserves the trace if the condition is fulfilled. Let $\rho$ denote the density operator of the investigated quantum system. The time evolution of an isolated quantum system is unitary, while all sorts of a non unitary dynamics reflect its interaction with an environment, described by a density operator $\sigma$. However, if we extend the system and study the dynamics of the total system, $\rho \otimes \sigma$, composed of the system under investigation and the environment, its time evolution remains unitary. The non unitary operation of $\rho$ emerges as an effect of the partial tracing with respect to the environment,

$$\rho \rightarrow \rho' = \Phi(\rho) = \text{Tr}_{\text{env}}\left[U(\rho \otimes \sigma)U^\dagger\right].$$  

(3.5)
The above form is called as *environmental representation* of the map $\Phi$. The entire process may be considered as a composition of three basic steps: adding an ancilla, unitary transformation, and partial tracing. The forms (3.2) and (3.3) are equivalent in the sense that any quantum operation may be written either way. Both representations are not unique, but as discussed in section IV, the notion of a dynamical matrix allows one to define a distinguished, canonical Kraus form.

Let the principal $N$–dimensional system $\rho$ be subjected to an operation defined by the $kN$ dimensional matrix $U$ and an initially pure state of the environment $\sigma = |\nu\rangle\langle\nu|$, and may construct an environmental form \[9, 67\]. For instance take the first $N$ atoms treated as a vector in the composed Hilbert–Schmidt space $\mathcal{H}_N$, and the general question of the minimal size of $\mathcal{H}_N$, and may be selected arbitrarily. $\mathcal{H}_N$ needs not to exceed $N^2$, the maximal number of Kraus operators required. If the environment is initially in a mixed state, its weights coefficients $q_\nu$ are needed to specify the operation. Counting the number of parameters one could thus speculate that the action of any quantum operation may be simulated by a coupling with a mixed state of the environment of size $kN$. Since the fixed environmental state $|\nu\rangle\langle\nu|$ belongs to the $k$-dimensional Hilbert space $\mathcal{H}_\nu$, the expression $\langle\mu|U|\nu\rangle$ represents a square matrix of size $N$, which we shall call $A_\mu$. In the double index notation, introduced above, any element of the unitary matrix is denoted by $U_{\mu\nu}^m$, while the matrix $A_\mu = \langle\mu|U|\nu\rangle$ consists of elements

$$A_{mn}^{(\mu)} = \langle m, \mu | U | n, \nu \rangle = U_{mn}^\mu.$$  \hspace{1cm} (3.7)

It is easy to see that (3.6) takes the operator sum form, $\sum_{\mu=1}^k A_\mu \rho A_\mu^\dagger$. Moreover, due to unitarity of $U$ the operators $A_\mu$ satisfy the completeness relation

$$\sum_{\mu=1}^k A_\mu A_\mu^\dagger = \sum_{\mu=1}^k \langle \nu|U^\dagger |\mu\rangle \langle \mu|U |\nu\rangle = \langle \nu|U^\dagger U |\nu\rangle = \mathbb{1}_N \hspace{1cm} (3.8)$$

and may be considered as Kraus operators. Every element of a given matrix $A_\mu$ belongs to one of the $N^2$ blocks of size $k$ of the unitary matrix $U$. However, if we reorder it constructing $U_{mn}^F = U_{knm}$, then each matrix $A_\mu$ is just a truncation of the flipped matrix $U^F$, since $A_{mn}^{(\mu)} = U_{knm}^F$ represents its minor.

If the initial state of the environment in the representation (3.6) is chosen to have full rank, $\sigma = \sum_{\nu=1}^k q_\nu |\nu\rangle\langle\nu|$, the operator sum representation consists of $k N$ terms

$$\rho' = \Phi(\rho) = \text{Tr}_\text{env} \left[ U \left( \rho \otimes \sum_{\nu=1}^k q_\nu |\nu\rangle\langle\nu| \right) U^\dagger \right] = \sum_{l=1}^{kN} A_l \rho A_l^\dagger \hspace{1cm} (3.9)$$

where $A_l = \sqrt{q_\nu} |\mu\rangle |\nu\rangle$ and $l = \mu + \nu (k-1)$.

In this way we have shown that for any operation written in the environmental form (3.6) we may find a corresponding Kraus form. Conversely, for any quantum operation written in the Kraus form (3.2) consisting of $k$ operators we may construct an environmental form (3.6). For instance take the first $N$ columns of a unitary matrix $U$ of size $k N$ are constructed of $k$ Kraus operators as defined in (3.6). Due to the completeness relation (3.8) they are normalized and orthogonal. The matrix $U$ has to be completed by $N(k-1)$ complex orthogonal vectors; they do not influence the quantum operation and may be selected arbitrarily.

If the initial state of the environment is pure its dimensionality $k$ of $\mathcal{H}_\nu$ needs not to exceed $N^2$, the maximal number of Kraus operators required. If the environment is initially in a mixed state, its weights coefficients $q_\nu$ are needed to specify the operation. Counting the number of parameters one could thus speculate that the action of any quantum operation may be simulated by a coupling with a mixed state of the environment of size $N$. However, this is not the case: already for $N = 2$ there exist operations which have to be simulated with 3–dimensional environment \[99, 111\], and the general question of the minimal size of $\mathcal{H}_\nu$ remains open.

It is also illuminating to discuss a special case of the problem, in which the initial state of the $N$–dimensional environment is maximally mixed, $\sigma = \rho_\nu = \mathbb{1}_N/N$. The unitary matrix $U$ of size $N^2$, defining the map, may be treated as a vector in the composed Hilbert–Schmidt space $\mathcal{H}_{N^2} \otimes \mathcal{H}_{N^2}$ and represented in its Schmidt form (3.7), $U = \sum_{i=1}^{N^2} \sqrt{\lambda_i} \hat{A}_i \otimes |\hat{A}_i^\dagger\rangle\langle\hat{A}_i^\dagger|$, where $\lambda_i$ are eigenvalues of $(U^R)U^R$. Since the operators $\hat{A}_i$, obtained by reshaping eigenvectors of $(U^R)U^R$, form an orthonormal basis in $\mathcal{H}_{N^2}$, the procedure of partial tracing leads to the Kraus form consisting of $N^2$ terms:

$$\rho' = \Phi_U(\rho) = \text{Tr}_\text{env} \left[ U (\rho \otimes \mathbb{1}_N) U^\dagger \right] = \text{Tr}_\text{env} \left[ \sum_{i=1}^{N^2} \sum_{j=1}^{N^2} \sqrt{\lambda_i \lambda_j} \left( \hat{A}_i \rho \hat{A}_i^\dagger \right) \otimes \left( \frac{1}{N} \hat{A}_i^\dagger \hat{A}_i^\dagger \right) \right] = \frac{1}{N} \sum_{i=1}^{N^2} \lambda_i \hat{A}_i \rho \hat{A}_i^\dagger.$$

$$\hspace{1cm} (3.10)$$
Operations, for which there exist a unitary matrix $U$ providing a representation in the above form, we shall call unistochastic channels. In a way, these maps are analogous to classical transformations given by unistochastic matrices, $\tilde{\rho}' = T\tilde{\rho}$, where $T_{ij} = |U_{ij}|^2$, since both dynamics are uniquely determined by a unitary matrix $U$ – of sizes $N$ and $N^2$ in the classical and the quantum cases, respectively.

In general one may consider maps analogous to $\Phi_D$ with an arbitrary size of the environment. In particular we define generalized, $K$–unistochastic maps, determined by a unitary matrix $U(N^{1+K})$, in which the environment of size $N^K$ is initially in the maximally mixed state, $N^{-K}\mathbb{1}_{N^K}$. Such operations were analyzed in context of quantum information processing [54, 85], and, under the name 'noisy maps', by studying reversible transformations from pure to mixed states [40]. By definition, 1–unistochastic maps are unistochastic.

For any unistochastic map the standard Kraus form (3.10) is obtained by rescaling the operators, $A_i = \sqrt{\lambda_i/N} \hat{A}_i$. Note that the matrix $U$ is determined up to a local unitary matrix $V$, in a way, these maps are analogous to classical transformations given by unistochastic matrices, $\Phi_U$. Operations, for which there exist a unitary matrix $U$, generating the same unistochastic map, $\Phi_U = \Phi_{U'}$.

IV. DYNAMICAL MATRIX

A density matrix $\rho$ of finite size $N$ may be treated as a vector $\hat{\rho}$ reshaped according to (2.1). The action of a linear superoperator $\Phi: \rho \rightarrow \rho'$ may thus be represented by a matrix $L$ ("L" like linear) of size $N^2$

$$\rho' = L\hat{\rho} \quad \text{or} \quad \rho'_{\mu\nu} = L^\mu_{\nu\rho}\rho_{\rho\nu}, \quad (4.1)$$

where summation over repeated indices is understood. Nonhomogeneous linear maps $\rho' = L'\rho + \delta$ may also be described in this way. To obtain the homogeneous form (4.1) it suffices to substitute the matrix $L^\mu_{\nu\rho}$ by $L^\mu_{\nu\rho} = L^\mu_{\nu\rho} + \sigma_{\mu\rho}\delta_{\nu\rho}$.

We require that the image $\rho'$ is a density matrix, so it is Hermitian, positive, and normalized. These three conditions impose constraints on the matrix $L$:

\begin{enumerate}
  \item $\rho' = (\rho')^\dagger \quad \Rightarrow \quad L^\mu_{\nu\rho} = L^\mu_{\nu\rho} \quad \text{so} \quad L^* = L^F$, \quad (4.2)
  \item $\rho' \geq 0 \quad \Rightarrow \quad L^\mu_{\nu\rho}\rho_{\rho\nu} \geq 0 \quad \text{for any state } \rho$, \quad (4.3)
  \item $\text{tr}\rho' = 1 \quad \Rightarrow \quad \sum_{\mu=1}^N L^\mu_{\rho\nu} = \delta_{\rho\nu}$. \quad (4.4)
\end{enumerate}

Note that (4.2) is not the condition of Hermicity and in general the matrix $L$ representing the operation $\Phi$ is not Hermitian. However, if we resuffle it according to (2.10) and define the dynamical matrix

$$D_\Phi \equiv L^R \quad \text{so that} \quad D^\mu_{\nu\rho} = L^\mu_{\nu\rho}, \quad (4.5)$$

than $D_\Phi$ is Hermitian, $D = D^\dagger$, due to (4.2). The linear superoperator $L$ is then uniquely determined by the dynamical matrix, since $L = L^R$. The notion of dynamical matrix was introduced already in 1961 by Sudarshan, Mathews and Rau [94]. Later such matrices were used by Choi [19] and are sometimes called Choi matrices [30].

What conditions must be satisfied by a Hermitian matrix $D$ of size $N^2$ to be a dynamical matrix? The trace condition (4.3), rewritten below for the matrix $D$, determines its trace

$$\text{Tr}_A D = \sum_{m=1}^N D^\mu_{\nu\rho} = \delta_{\mu\nu} \quad \Rightarrow \quad \text{Tr}_D = \sum_{m=1}^N \sum_{\mu=1}^N D^\mu_{\nu\rho} = \sum_{\mu=1}^N \delta_{\mu\nu} = N. \quad (4.6)$$

The positivity condition (4.3) implies that for any states $|x\rangle$ and $\rho$ the expectation value $\langle x|D^R\rho|x\rangle$ is not negative. Assuming that the initial state is pure, $\rho = |y\rangle\langle y|$ so that $\rho_{\mu\nu} = y_\mu y_\nu^*$, we obtain

$$\langle x|D^R(|y\rangle\langle y|)|x\rangle = \langle (x|\otimes (|y\rangle\otimes |x\rangle) \rangle D((|y\rangle\otimes |x\rangle) \geq 0, \quad (4.7)$$

since the double sum $D^\mu_{\nu\rho}y_\mu y_\nu^*$ represents as well the matrix $D^R(|y\rangle\langle y|)$ as well as $\langle y|D|y\rangle$. Thus the dynamical matrix $D$ must be positive on product states $|y\rangle\otimes |x\rangle$. This property is called block–positivity. In fact Jamiołkowski proved, in 1972, that the converse is also true: if property (4.7) is satisfied then the map $\Phi$ determined by matrix $D$ is positive [48] – see section VIII.
Positivity of $D_\Phi$ is a sufficient, albeit not necessary requirement for (4.7). If $D_\Phi \geq 0$ then the map $\Phi$ is completely positive [10, 29, 32, 34, 97]. To prove this let us represent $D_\Phi$ by its spectral decomposition,

$$D_\Phi = \sum_{i=1}^{k} d_i |\chi_i\rangle \langle \chi_i|,$$

so that

$$D_{\mu\nu} = \sum_{i=1}^{k} d_i \chi_{\mu i}^{(i)} \chi_{\nu i}^{(i)}.$$  

(4.8)

Here $k$ denotes the rank of $D_\Phi$ so $k \leq N^2$, while $\chi_{\mu i}^{(i)}$ represent $N \times N$ matrices obtained by reshaping the eigenvectors $|\chi_i\rangle$ of length $N^2$. Due to (4.6) the sum of all eigenvalues $d_i$ is equal to $N$. If $D_\Phi$ is positive, all its eigenvalues are nonnegative, so we may rescale the eigenvectors defining the operators $A_i = A^{(i)}$

$$A_{\mu i}^{(i)} \equiv \sqrt{d_i} \chi_{\mu i}^{(i)}, \quad i = 1, 2, \ldots, k,$$

so that

$$D_{\mu\nu} = \sum_{i=1}^{k} A_{\mu i}^{(i)} A_{\nu i}^{(i)} = \sum_{i=1}^{k} (A_i \otimes A_i) R_i.$$  

(4.10)

If all Kraus operators are real $A_i = \bar{A}_i$, or purely imaginary, $A_i = -\bar{A}_i$, then the Hermitian dynamical matrix is real and hence symmetric, $D_\Phi = D_\Phi^T$. Reshuffling the dynamical matrix $D$ (of the size $N^2$, with a finite $N$), we may write

$$L = \sum_{i=1}^{k} A_i \otimes \bar{A}_i = \sum_{i=1}^{k} d_i \chi^{(i)} \otimes \bar{\chi}^{(i)}.$$  

(4.11)

The latter form may be thus considered as a Schmidt decomposition [27] of the superoperator $L$ for a CP–map, since the non-negative eigenvalues of $D$ are simultaneously Schmidt coefficients of $L = D^R$.

Alternatively one may find a matrix $A$ of size $N^2 \times k$ such that $D_\Phi = AA^\dagger$. This is always possible since $D$ is positive. Then the operator $A^{(i)}$ is obtained by reshaping the $i$–th column of $A$ into a square matrix. Using the eigen representation of $D_\Phi$ the quantum map $\Phi$ defined in (4.1) becomes

$$\rho_{\mu\nu}^i = D_{\mu\nu} \rho_{\mu\nu} = \sum_{i=1}^{k} A_{\mu i}^{(i)} \rho_{\mu\nu} A_{\nu i}^{(i)}.$$  

(4.12)

and it may be written in the canonical Kraus form

$$\rho' = \sum_{i=1}^{k} d_i \chi^{(i)} \rho \chi^{(i)} \dagger = \sum_{i=1}^{k} A_i \rho A_i^\dagger.$$  

(4.13)

Let us compute the matrix $E = \sum_{i=1}^{k} A_i^\dagger A_i$,

$$E_{\mu\nu} = \sum_{i=1}^{k} A_{\mu i}^{(i)} A_{\nu i}^{(i)} = \sum_{i=1}^{k} d_i \chi_{\mu i}^{(i)} \chi_{\nu i}^{(i)} = D_{\mu\nu}.$$  

(4.14)

and therefore $E = \text{Tr}_A D_\Phi$. Due to the trace preservation constraint (4.6) $E = 1$, so the operators $A_i$ satisfy the completeness relation (4.3). Hence (4.13) is equivalent to the Kraus form (4.2) and represents a trace preserving CP map. We have thus shown that any positive dynamical matrix $D$, which satisfies the condition (4.6), specifies uniquely a quantum operation, hence any $N$-positive map $\Phi$ leads to a positive matrix $D_\Phi$, so $\Phi$ is completely positive.

On the other hand, the Kraus representation (4.2) is not unique – two sets of the Kraus operators $A_i$, $i = 1, \ldots, l$ and $B_j$, $j = 1, \ldots, n$ represent the same operation if and only if the dynamical matrices given by (4.11) are equal. This is the case if there exists a unitary matrix $V$ of size $mN$ such that $A = BV$ so that the dynamical matrices both sets generate, are equal,

$$D = AA^\dagger = BV (BV)^\dagger = BB^\dagger.$$  

(4.15)

Here $m = \max\{l, n\}$ and the shorter list of the Kraus operators is formally extended by $|l - n|$ zero operators.

In principle the number of Kraus operators in (4.2) may be arbitrarily large. However, for any operation one may find its Kraus form consisting of not more operators than the rank $k$ of the dynamical matrix $D$. This Kraus rank
TABLE II: Quantum operations $\Phi: \mathcal{M}(N) \to \mathcal{M}(N)$: properties of superoperator $L$ and dynamical matrix $D_\Phi = L^R$

| Matrices | Superoperator $L = D^R$ | Dynamical matrix $D_\Phi$ |
|----------|--------------------------|---------------------------|
| Hermicity | spectrum is symmetric $\Rightarrow \text{tr}L \in \mathbb{R}$ | $\text{tr}D_\Phi = N$ |
| (right) Eigenvectors | or transient corrections | Kraus operators |
| Eigenvalues | $|z_i| \leq 1$ decay rates | weights of Kraus operators, $d_i \geq 0$ |
| Unitary evolution $D_\Phi = (U \otimes U^*)^R$ | $||L||_2 = N$ | $S(\vec{d}) = 0$ |
| Coarse graining | $||L||_2 = \sqrt{N}$ | $S(\vec{d}) = \ln N$ |
| Complete depolarisation, $D_\Phi = \mathbb{1}$ | $||L||_2 = 1$ | $S(\vec{d}) = 2\ln N$ |

will never exceed the dimension of the dynamical matrix equal to $N^2$. Moreover, the Kraus operators $A_i$ may be chosen to be orthogonal. To find such a canonical Kraus form given by (4.13) for an arbitrary operation $\Phi$ it is enough to find its linear matrix $L$, reshuffle it to obtain the dynamical matrix $D_\Phi$, diagonalize it, and out of its eigenvalues $d_i$ and reshaped eigenvectors $|\chi_i\rangle$ construct by (4.9) the orthogonal Kraus operators $A_i$. They satisfy

$$\langle A_i | A_j \rangle = \text{Tr}A_i^\dagger A_j = \sqrt{d_i d_j} \langle \chi_i | \chi_j \rangle = d_i \delta_{ij}. \quad (4.16)$$

In a sense the Kraus form (3.2) of a quantum operation $\Phi$ can be compared with an arbitrary decomposition of a density matrix, $\rho = \sum_i p_i |\phi_i\rangle \langle \phi_i|$, while its eigen decomposition corresponds to the canonical Kraus form of the map, for which $||A_i||^2 = d_i$. In the generic case of a nondegenerate dynamical matrix $D$, the canonical Kraus form is specified uniquely, up to free phases, which may be put in front of each Kraus operator $A_i$.

As discussed in section VIII such an analogy between the quantum maps (dynamics) and the quantum states (kinematics) may be pursued much further. Let us state at this point that the dynamical matrix is a linear function of the quantum operations $\Phi$ and $\Psi$ in the sense that

$$D_{a\Phi + b\Psi} = aD_\Phi + bD_\Psi. \quad (4.17)$$

An arbitrary quantum operation $\Phi$ is uniquely characterized by any of the two matrices $L$ or $D_\Phi = L^R$, but the meaning of their spectra is entirely different. The dynamical matrix $D_\Phi$ is Hermitian, while $L$ is not and in general its eigenvalues $z_i$ are complex. Let us order them according to their moduli, $|z_1| \geq |z_2| \geq \cdots |z_N| \geq 0$. A continuous linear operation $\Phi$ sends the convex compact set $\mathcal{M}^{(N)}$ into itself. Therefore, due to the fixed–point theorem, this transformation has a fixed point – an invariant state $\sigma_1$ such that $L\sigma_1 = \sigma_1$. Thus $z_1 = 1$ and all eigenvalues fulfill $|z_i| \leq 1$, since otherwise the assumption that $\Phi$ is positive would be violated.

The trace preserving condition applied to the eigen equation $L\sigma_1 = z_1\sigma_1$, implies that if $z_1 \neq 1$ than $\text{tr}(\sigma_1) = 0$. If $r = |z_2| < 1$ then the matrix $L$ is primitive and all states converge to the invariant state $\sigma_1$. If $L$ is diagonalizable (there is no degeneracy in the spectrum or there exists no nontrivial blocks in the Jordan decomposition of $L$, so that the number of right eigenvectors $\sigma_i$ is equal to the size of the matrix $N^2$), then any initial state $\rho_0$ may be expanded in the eigenbasis of $L$,

$$\rho_0 = \sum_{i=1}^{N^2} c_i \sigma_i \quad \text{while} \quad \rho_i = L^i \rho_0 = \sum_{i=1}^{N^2} c_i z_i^i \sigma_i. \quad (4.18)$$

Therefore $\rho_0$ converges exponentially fast to the invariant state $\sigma_1$ with the decay rate not smaller than $-\ln r$ and the right eigenstates $\sigma_i$ for $i \geq 2$ play the role of the transient traceless corrections to $\rho_0$. The super-operator $L$ sends Hermitian density matrices into Hermitian density matrices, $\rho_1 = \rho_1 = L\rho_0 = L\rho_0^\dagger$, so

$$L\chi = z\chi \quad \text{then} \quad L\chi^\dagger = z^* \chi^\dagger, \quad (4.19)$$

and the spectrum of $L$ (contained in the unit circle) is symmetric with respect to the real axis. Thus the trace of $L$ is real, as follows also from the Hermicity of $D_\Phi = L^R$. 

On the other hand, the real eigenvalues \( d_j \) of the dynamical matrix \( D_\Phi \) satisfy the normalization condition \( \sum_j d_j = N \), which we assume to be finite. If the map \( \Phi \) is completely positive all eigenvalues \( d_j \) of \( D_\Phi \) are non-negative, and the matrix \( \rho_\Phi \equiv D_\Phi/N \) may be interpreted as a density matrix acting in \( \mathcal{H}_{N^2} \). The eigenvalues of \( \rho_\Phi \), equal to \( \tilde{d} = \tilde{d}/N \), determine the weights of different operators \( A_j \) contributing to the canonical Kraus form of the map given by (4.14). To characterize this probability vector quantitatively we use the Shannon entropy to define the \emph{entropy of an operation} \( \Phi \),

\[
S(\Phi) \equiv S(\frac{1}{N}\tilde{d}) = -\sum_{i=1}^{N^2} (d_i/N) \ln(d_i/N) = S_N(\rho_\Phi),
\]

(4.20)
equal to the von Neumann entropy of \( \rho_\Phi \). In order to characterize, to what extent the distribution of the elements of the vector \( \tilde{d} \) is uniform one may also use other quantities like linear entropy, participation ratio or generalized Rényi entropies. If \( S(\tilde{d}) = 0 \), the dynamical matrix \( D_\Phi \) is of rank one, so the state \( \rho_\Phi \) is pure. Then Eq. (4.10) reduces to \( D_{\mu}\nu = U_{\mu}\nu U_{\nu}^* \), while \( L = U \otimes U^* \) and the map \( \Phi \) represents a unitary rotation. The larger the entropy \( S \) of an operation, the more terms enter effectively into the canonical Kraus form, and the larger are effects of decoherence in the system.

For any finite \( N \) the entropy is bounded by \( S_{\max} = 2 \ln N \), which is achieved for the rescaled identity matrix, \( D = \mathbb{1}_{N^2}/N \). This matrix represents the \emph{completely depolarizing channel} \( \Phi_* \), such that any initial state \( \rho \) is transformed into the maximally mixed state,

\[
\Phi_*(\rho) = \rho_* = \mathbb{1}/N \quad \text{for any state } \rho.
\]

(4.21)
Under the action of this map complete decoherence takes place already after the first iteration. It is easy to see that the spectrum of the corresponding superoperator \( L_* = \frac{1}{N}(\mathbb{1})^R \) consists of \( z_1 = 1 \) and \( z_i = 0 \) for \( i \geq 2 \). In general the norm of the superoperator, \( ||L||_2 = \sqrt{\text{Tr}LL^\dagger} \), may thus be considered as another quantity characterizing the decoherence induced by the map. The norm \( ||L||_2 \) varies from unity for the completely depolarizing channel \( \Phi_* \) (total decoherence) to \( N \) for any unitary operation (no decoherence). Both quantities are connected, since \( ||L||_2^2 = \text{tr}D^2 \), is a function of the Rényi entropy of order \( \alpha = 2 \) of the spectrum of \( D \) rescaled by \( 1/N \). Making use of the monotonicity of the Rényi entropies \([11]\) we get \( ||L||_2 \geq N \exp(-S(\Phi)/2) \).

An alternative way to characterize the properties of a superoperator is to use its trace norm,

\[
\gamma = ||L||_1 = \text{Tr}|L| = \text{Tr}\sqrt{LL^\dagger} = \sum_{i=1}^{N^2} \xi_i,
\]

(4.22)
where \( \xi_i \) are the singular values of \( L = D^R \). As discussed in \([17, 39]\) this quantity is useful to determine separability of the state associated with the dynamical matrix, \( \rho_\Phi = D/N \).

If the set of Kraus operators \( \{A_i\}_{i=1}^k \) determines a quantum operation \( \Phi \) then for any two unitary matrices \( V \) and \( W \) of size \( N \) the set of operators \( A_i^\dagger = VA_iW \) satisfies the relation (3.3) and defines the operation

\[
\rho \to \rho' = \Phi_{VW}(\rho) = \sum_{i=1}^k A_i^\dagger \rho A_i^\dagger = V \left( \sum_{i=1}^k A_i(V\rho V^\dagger)A_i^\dagger \right) V^\dagger.
\]

(4.23)
The operations \( \Phi \) and \( \Phi_{VW} \) are in general different, but \emph{unitarily similar}, in a sense that the spectra of the dynamical matrices are equal. Thus their generalized entropies are equal, so \( S(\Phi) = S(\Phi_{VW}) \) and \( ||L||_2 = ||L_{VW}||_2 \). The latter equality follows directly from the following law of the transformation of superoperators,

\[
L_{VW} = (V \otimes V^*)L(W \otimes W^*),
\]

(4.24)
which is a consequence of (4.11).

\textbf{V. UNITAL & BISTOCHASTIC MAPS}

Consider a completely positive quantum operation \( \Phi \) defined by Kraus operators \([12]\). If the set of \( k \) operators \( A_i \) satisfies the relation,

\[
\sum_{i=1}^k A_i A_i^\dagger = 1 = \text{tr}_B D
\]

(5.1)
the operation is unital (or exhaustive), i.e. the maximally mixed state $ρ_*=1/N$ remains invariant, $Φ(ρ_*)=1/N \sum_{i=1}^k A_iA_i^\dagger = ρ_*$. Since $(ρ_*)_{mn}=1/N δ_{mn}$ then the elements of $Φ(ρ_*)$ are $1/N L_{mn} δ_{mν} = 1/N D_{mn}$, which explains the right hand side equality in (5.1), related to the properties of the dynamical matrix $D$.

Observe the similarity between the condition (5.3) for the preservation of trace and the unitality constraint (5.1). Unitality imposes that the sum of all elements in each row of the corresponding matrix $M$ defined by (5.3) is equal to one. Hence for any map $Φ$ which is simultaneously trace preserving and unital, the Kraus matrix $M$ is doubly-stochastic (bistochastic). Therefore a trace preserving, unital completely positive map is called a bistochastic map (6, 64), and may be considered as a noncommutative analogue of the action of a bistochastic matrix $B$ on a probability vector — see table III. In the former case, the maximally mixed state $ρ_*$ is $Φ$–invariant, while the uniform probability vector is an invariant vector of $B$.

If all Kraus operators are Hermitian, $A_i = A_i^\dagger$, the channel is bistochastic but this is not a necessary condition. For example, unitary evolution may be considered as the simplest case of the bistochastic map with $k = 1$. A more general class of bistochastic channels is given by a convex combination of unitary operations, also called random external fields (REF) (6).

For any quantum channel $Φ(ρ)$ one defines its dual channel $Φ^∗(ρ)$, such that the Hilbert–Schmidt scalar product satisfies $⟨Φ(σ)|ρ⟩ = ⟨σ|Φ^∗(ρ)⟩$ for any states $σ$ and $ρ$. If a CP map is given by the Kraus form $Φ(ρ) = ∑_i A_i ρ A_i^\dagger$, the dual channel reads $Φ^∗(ρ) = ∑_i A_i^\dagger ρ A_i$. Making use of (4.10) we obtain a link between the dynamical matrices representing dual channels,

$$L^*_{Φ} = (L^*_{Φ})^T = (L^T_{Φ})^T \quad \text{and} \quad D^*_{Φ} = (D^*_{Φ})^T = (D^T_{Φ})^T = D^T_{Φ}.$$  \hspace{1cm} (5.3)

Since neither the transposition nor the flip modify the spectrum of a matrix, the spectra of the dynamical matrices for dual channels are the same, as well as their entropies, $S(Φ) = S(Φ^*)$.

Comparing the conditions (5.3) and (5.1) we see that if channel $Φ$ is trace preserving, its dual $Φ^*$ is unital, and conversely, if channel $Φ$ is unital then $Φ^*$ is trace preserving. Thus the channel dual to a bistochastic one is bistochastic.

For any quantum operation $Φ$ given by the Kraus form (6.2) one defines its effect by $E = ∑_i A_i A_i^\dagger$. Due to Eq. (5.1) the effect is obtained by partial trace of the dynamical matrix, $E = Tr_B D$, so it is Hermitian and positive. Since $E(Φ) = 1/N Φ(ρ_*)$, it is clear that the effect of any operation does not depend of the particular choice of the Kraus operators used to represent it. For bistochastic maps $Φ(ρ_*) = ρ_*$ and $E = 1$.

Bistochastic channels are the only ones which do not decrease the von Neumann entropy of any state they act on. To see this consider the image of the maximally mixed state, with maximal entropy in $N$. If the map is not unital, (the channel is not bistochastic), then $ρ^* = Φ(ρ_*)$ differs from $ρ_*$, so its entropy decreases. As an important example of bistochastic channels consider the coarse graining operation, which sets all off-diagonal elements of a density matrix to zero, $Ψ_{CG}(ρ) = diag(ρ)$. It is described by the diagonal dynamical matrix, $D_{mn}^{CG} = δ_{mn} δ_{μν} δ_{mμ}$, with $N$ elements equal to unity.

Let us analyze in some detail the set $BU_N$ of unistochastic operations, for which there exists the representation (8.10). The initial state of the environment is maximally mixed, $σ = ρ_*=1/N$, so the quantum map $Ψ_U$ is determined by a unitary matrix $U$ of size $N^2$. The reshaped Kraus operators $A_i$ are proportional to the eigenvectors (4.39) of the dynamical matrix $D_{Ψ_U}$. On the other hand, they enter also the Schmidt decomposition (2.7) of $U$ as shown in (8.10), and are proportional to the eigenvectors of $(U^R)\dagger U^R$. Therefore

$$D_{Ψ_U} = 1/N (U^R)^\dagger U^R \quad \text{so that} \quad L = 1/N [(U^R)^\dagger U^R]^R.$$  \hspace{1cm} (5.4)

We have thus arrived at an important result: for any unistochastic map the spectrum of the dynamical matrix $D$ is given by the Schmidt coefficients, $d_i = λ_i/N$, of the unitary matrix $U$ treated as an element of the composite HS space. Hence the entropy of the operation $S(Ψ_U)$ is equal to the entanglement entropy of the unitary matrix, $S(U)$. 
TABLE III: Quantum maps acting on density matrices and given by positive definite dynamical matrix $D \geq 0$ versus classical Markov dynamics on probability vectors defined by transition matrix $T$ with non-negative elements

| Quantum | completely positive maps: | Classical | Markov chains given by: |
|---------|--------------------------|-----------|------------------------|
| $S^Q_1$ | Trace preserving, $\Tr_A D = 1$ | $S^C_1$ | Stochastic matrices $T$ |
| $S^Q_2$ | Unital, $\Tr_B D = 1$ | $S^C_2$ | $T^T$ is stochastic |
| $S^Q_3$ | Unital & trace preserving maps | $S^C_3$ | Bistochastic matrices $B$ |
| $S^Q_4$ | Maps with $A_i = A_i^\dagger$ $\Rightarrow D = D^T$ | $S^C_4$ | Symmetric bistochastic matrices, $B = B^T$ |
| $S^Q_5$ | Unistochastic operations, $D = U R (U R^\dagger)$ | $S^C_5$ | Unistochastic matrices, $B_{ij} = |U_{ij}|^2$ |
| $S^Q_6$ | Orthostochastic operations, $D = O R (O R^\dagger)$ | $S^C_6$ | Orthostochastic matrices, $B_{ij} = |O_{ij}|^2$ |
| $S^Q_7$ | Unitary transformations | $S^C_7$ | Permutations |

Moreover, the linear entropy of $U$ studied in [112] is a function of the norm of the superoperator, $E(U) = 1 - \sum_i \lambda_i^2 = 1 - \|L\|_2^2/N^2$. It vanishes for any local operation, $U = U_1 \otimes U_2$, for which the superoperator is unitary, $L = U_1 \otimes U_1^\dagger$ so $\|L\|_2^2 = N^2$. The resulting unitary operation is an isometry, and can be compared with a permutation $S^C_4$ acting on the simplex $\Delta_{N-1}$ of classical probability vectors. If the matrix $U$ is orthogonal the corresponding dynamical matrix is symmetric, $D_{\Phi_O} = (O R)^\dagger O R = D_{\Phi_O}^R$. The corresponding operation will be called an orthostochastic map, as listed in Table [III]. The spaces listed there satisfy the following relations $S_1 \cap S_2 = S_3$ and $S_3 \supset S_5 \supset S_6$ and $S_5 \supset S_7$ in both, classical and quantum setups. However, the analogy is not exact: the inclusions $S^C_4 \subset S^C_3$ and $S^C_5 \subset S^C_3$ and $S^C_6 \subset S^C_4$ do not have their counterparts. Note that unitary (orthogonal) matrices defining quantum maps $\mathcal{M}^{(N)} \to \mathcal{M}^{(N)}$ are of size $N^2$ while these determining Markov chains $\Delta_{N-1} \to \Delta_{N-1}$ are of size $N$. Note that already for $N = 2$ not all bistochastic maps are unistochastic [72].

VI. ONE QUBIT MAPS

In the simplest case $N = 2$ the quantum operations are called binary channels. In general, the space $\mathcal{CP}_N$ is $N^4 - N^2$ dimensional. Hence the space $\mathcal{CP}_2$ of binary channels has 12 dimensions and there exist several ways to parametrise it [29, 53]. The dynamical matrix provides a straightforward, but not very transparent method to achieve this goal. Any Hermitian matrix $D$ of size 4, which satisfies $\tr_A D = 1$ may be written as

$$D = \begin{bmatrix}
\frac{1}{2} + a & x & y & z \\
\frac{1}{2} - b & \frac{1}{2} & w & -u \\
\frac{1}{2} - a & -x & \frac{1}{2} & \bar{v} \\
\frac{1}{2} & \bar{w} & -u & \frac{1}{2} + b
\end{bmatrix},$$

(6.1)

where $a$ and $b$ are real and $x, y, z, u, w$ complex parameters. If they are adjusted in such a way to assure positivity of $D$, then this matrix represents a trace preserving CP map. Note that $D/N$ represents a certain density matrix in $\mathcal{M}^{(4)}$. If additionally $a = b$ and $y = u$ then the condition $\tr_B D = 1$ is fulfilled, so the map is bistochastic.

An alternative approach to the problem is obtained using the Stokes parametrisation, which involves Pauli matrices $\sigma_k$. Any state $\rho = (1 + \tau \cdot \sigma)/2$, is characterized by the Bloch vector $\vec{\tau}$. If $\rho' = \Phi(\rho)$ is represented by $\vec{\tau}'$, then any linear dynamics inside the Bloch ball may be described by an affine transformation of the Bloch vector

$$\vec{\tau}' = t \vec{\tau} + \vec{r},$$

(6.2)

where $t$ denotes a real matrix of size 3, while $\vec{r} = (\kappa_x, \kappa_y, \kappa_z)$ is the translation vector. It determines the image of the ball center, $\Phi(\rho_s) = (1 + \vec{\kappa} \cdot \sigma)/2$. For unital maps $\Phi(\rho_s) = \rho_s$ so $\vec{r} = 0$. Any positive map sends the Bloch ball into an ellipsoid which may degenerate to an ellipse, an interval or a point. Out of 12 real parameters in $\{t, \vec{r}\}$ 3 eigenvalues of $tt^\dagger$ determine the size of the ellipsoid, 6 related to the eigenvectors specify the orientation of its axis and the 3 parameters of the vector $\vec{r}$ characterize the position of its center.

The real matrix $t$ may be brought to the form, $t = O_1 \eta O_2$, where $O_1 \in O(3)$ and the diagonal matrix $\eta$ contains non-negative singular values of $t$. However, it is convenient to impose an extra condition that both orthogonal matrices...
represents proper rotations \((O_i \in SO(3))\), at the expense of allowing some components of the diagonal vector \(\vec{\eta}\) to be negative. This decomposition is not unique: the moduli \(|\eta_i|\) are equal to singular values of \(t\) and the sign of the product \(\eta_x\eta_y\eta_z = \det(t)\) is fixed. However, the signs of any two components of \(\vec{\eta}\) may be changed by conjugating the map with a Pauli matrix.

In general, for any one–qubit CP map \(\Phi\) one may find unitary matrices \(U\) and \(W\) of size 2 such that the unitarily similar operation \(\Phi U W\) defined by \((4.23)\) is represented by the diagonal matrix \(\eta\). For simplicity we may thus restrict ourselves to the maps for which the matrix \(t\) is diagonal and consists of the damping (distortion) vector, \(\vec{\eta} = (\eta_x, \eta_y, \eta_z)\).

In this case the ellipsoid has the form
\[
\left(\frac{x - \kappa_x}{\eta_x}\right)^2 + \left(\frac{y - \kappa_y}{\eta_y}\right)^2 + \left(\frac{z - \kappa_z}{\eta_z}\right)^2 = 1.
\]
(6.3)

The affine transformation \((4.2)\) determines the superoperator \(L\) of the map. Reshuffling the superoperator matrix according to \((4.5)\) we obtain the dynamical matrix
\[
D = L R = \begin{bmatrix}
1 + \eta_z + \kappa_z & 0 & \kappa_x + i\kappa_y & \eta_x + \eta_y \\
0 & 1 - \eta_z + \kappa_z & \eta_x - \eta_y & \kappa_x + i\kappa_y \\
\kappa_x - i\kappa_y & \eta_x - \eta_y & 1 - \eta_z - \kappa_z & 0 \\
\eta_x + \eta_y & \kappa_x - i\kappa_y & 0 & 1 + \eta_z - \kappa_z
\end{bmatrix},
\]
(6.4)
clearly a special case of \((6.1)\). For unital maps \(\vec{\kappa} = 0\) and the matrix \(D\) splits into two blocks and its eigenvalues are
\[
d_{0,3} = \frac{1}{2}[1 + \eta_z \pm (\eta_x + \eta_y)] \quad \text{and} \quad d_{1,2} = \frac{1}{2}[1 - \eta_z \pm (\eta_x - \eta_y)].
\]
(6.5)

Hence if the Fujiwara–Algoet conditions \(21\)
\[
(1 \pm \eta_z)^2 \geq (\eta_x \pm \eta_y)^2
\]
are fulfilled, the dynamical matrix \(D\) is positive definite and the corresponding positive map \(\Phi_{\vec{\eta}, \vec{\kappa}}\) is CP. This condition shows that not all ellipsoids located inside the Bloch ball may be obtained by acting on the ball with a CP map - see recent papers on one qubit maps \(21, 53, 77, 97, 103, 104, 106\).

Note that dynamical matrices of unital maps do commute, \([D_{\Phi_{\vec{\eta}}}, D_{\Phi_{\vec{\kappa}}}] = 0\). Hence they share the same set of eigenvectors. When reshaped they form the orthogonal set of Kraus operators consisting of the identity \(\sigma_0 = \mathbb{1}_2\), and the three Pauli matrices \(\vec{\sigma}\). Thus the canonical form of an arbitrary one–qubit bistochastic map reads
\[
\rho' = \Phi_{\vec{\eta}}(\rho) = \sum_{i=0}^{3} d_i \sigma_i \rho \sigma_i,
\]
(6.7)
which explains the name Pauli channels.

For concreteness let us distinguish some one-qubit channels. We are going to specify their translation and distortion vectors, \(\vec{\kappa}\) and \(\vec{\eta}\), since with use of the transformation \((4.23)\) we may bring the matrix \(t\) to its diagonal form.

Alternatively, the channels may be defined using the canonical Kraus form \((4.13)\) in which Kraus operators are given by the eigenvalues and eigenvectors of the dynamical matrix, \(A_i = \sqrt{d_i} \chi_i\). From \((6.7)\) it follows that for any \(N = 2\)
TABLE IV: Exemplary one–qubit channels: distortion vector $\vec{\eta}$, translation vector $\vec{\kappa}$ equal to zero for unital channels, rescaled Kraus spectrum $\vec{d}'$, and the Kraus rank $k$.

| Channels          | $\vec{\eta}$       | $\vec{\kappa}$ | unital | $\vec{d}'$ | $k$ |
|-------------------|---------------------|-----------------|--------|------------|-----|
| rotation          | $(1, 1, 1)$         | $(0, 0, 0)$     | yes    | $(1, 0, 0)$ | 1   |
| phase flip        | $(1 - p, 1 - p, 1)$ | $(0, 0, 0)$     | yes    | $(1 - p/2, p/2, 0, 0)$ | 2   |
| decaying          | $(\sqrt{1 - p}, \sqrt{1 - p}, 1 - p)$ | $(0, 0, p)$   | no     | $(1 - p/2, p/2, 0, 0)$ | 2   |
| depolarizing      | $[1 - x](1, 1, 1)$  | $(0, 0, 0)$     | yes    | $\frac{1}{4}(4 - 3x, x, x, x)$ | 4   |
| linear            | $(0, 0, q)$         | $(0, 0, 0)$     | yes    | $\frac{1}{4}(1 + q, 1 - q, 1 - q, 1 + q)$ | 4   |
| planar            | $(0, r, q)$         | $(0, 0, 0)$     | yes    | $\frac{1}{4}(1 + q + r, 1 - q - r, 1 - q + r, 1 + q - r)$ | 4   |

Bistochastic map the Kraus operators are $A_i = \sqrt{d_i}\sigma_i$. For the decaying channel, (also called amplitude–damping channel), which is not bistochastic, the eigenvectors of the dynamical matrix give

$$A_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \sqrt{1 - p} \end{bmatrix} \quad \text{and} \quad A_2 = \begin{bmatrix} 0 & \sqrt{p} \\ 0 & 0 \end{bmatrix}.$$ (6.8)

Basic properties of some selected maps are collected in Table IV and illustrated in Fig. 2.

The geometry of the set of bistochastic maps is simplest to understand for $N = 2$. As discussed in section V, this set coincides with the set of $N = 2$ random external fields, which may be defined as the convex hull of four unitary operations, $\sigma_0 = 1$, $\sigma_x$, $\sigma_y$, and $\sigma_z$. Thus, in agreement with (6.7), any one-qubit bistochastic map $\Phi \in \mathcal{B}_2$ may be written as a convex combination of four matrices $\sigma_j$, $j = 0, ..., 3$. Since $\sigma_j = -i \exp(i\pi\sigma_j/2)$, and the overall phase $-\pi$ is not relevant, each Pauli matrix represents the rotation of the Bloch ball around the corresponding axis by angle $\pi$. The distortion vectors $\vec{\eta}$ of four extremal maps $\sigma_j$ read $(1, 1, 1)$, $(1, -1, -1)$, $(-1, 1, -1)$, and $(-1, -1, 1)$, respectively. Hence, in accordance with the constraints (6.6), the set of bistochastic maps $\mathcal{B}_2$ written in the canonical form (with diagonal matrix $t$), forms a tetrahedron, see Fig. 3a. Its center is occupied by the completely depolarizing channel with $\vec{\eta} = \vec{0}$, which may be expressed as a uniform mixture of four extremal unitarities; $\Psi_+ = (\mathbb{I} + \sigma_x + \sigma_y + \sigma_z)/4$. Interestingly, the set of non unital channels with a fixed translation vector $\vec{\kappa} \neq 0$ forms a convex set which resembles a tetrahedron with its corners rounded.

![FIG. 3: Subsets of one–qubit maps: a) set $\mathcal{B}_2$ of bistochastic maps (unital & CP), b) set $T(\mathcal{B}_2)$ of unital & CcP maps, c) set of positive (decomposable) unital maps.](image)

Observe that in the generic case $|\eta_i| < 1$, which suggests that a typical one-qubit CP map is a contraction. This is true also for higher dimensions, $N > 2$. The monotone distances (e.g. the trace distance and the Bures distance) do not increase under the action of CP maps. Apart from unitary (antiunitary) operations, for which these distances are preserved, the transformation inverse to a quantum operation is not an operation any more: some mixed states are sent outside the set of positive operators.
VII. POSITIVE & DECOMPOSABLE MAPS

Quantum transformations which describe physical processes are represented by completely positive maps. Why should we care about maps which are not completely positive? On one hand it is instructive to realize that seemingly innocent transformations are not CP, and thus do not correspond to any physical process. On the other hand maps which are positive, not completely positive provide a crucial tool in the investigation of entangled mixed states [37, 38, 82].

Consider the transposition of a density matrix in a certain basis $T : \rho \rightarrow \rho^T$. The corresponding superoperator $L_T$ entering [41] has the form $(L_T)_{ij} = \delta_{ij} \delta_{\mu\nu}$, and equals the dynamical matrix, $L_T = L^L_T = D_T$. This is a permutation matrix which contains $N^2$ diagonal entries equal to unity and $N(N-1)/2$ blocks of size two. Thus its spectrum, $\text{spec}(D_T)$, consists of $N(N+1)/2$ eigenvalues equal to unity and $N(N-1)/2$ eigenvalues equal to $-1$, which is consistent with the constraint $\text{tr}D = N$. The matrix $D_T$ is not positive, so the transposition $T$ is not completely positive. Another way to reach this conclusion is to act with the extended map of partial transposition on the maximally entangled state [82] and to check that $[T \otimes 1](|\psi\rangle\langle\psi|)$ has negative eigenvalues.

The transposition of an $N$–dimensional Hermitian matrix $D$, which changes the signs of the imaginary part of the elements $D_{ij}$, may be viewed as a reflection with respect to the $N(N+1)/2 - 1$ dimensional hyperplane, so the remaining $N(N-1)/2$ components do change their signs. As shown in Fig. 4 this geometrical interpretation is simple to visualize for $N = 2$: the transposition corresponds to a reflection of the Bloch ball with respect to the $(x, z)$ plane - the $y$ coordinate changes its sign. Note that rotation of the Bloch ball around the axis $\pi$, realized by a unitary operation, $\rho \rightarrow \sigma_z \rho \sigma_z$, also exchanges the ‘western’ and the ‘eastern’ hemispheres, but is completely positive.

As discussed in section [41] a given map $\Phi$ is not CP, if the corresponding dynamical matrix $D$ contains a negative eigenvalue. Let $m \geq 1$ denote the number of the negative eigenvalues (in short, the neg rank of $D$). Then the spectral decomposition of $D$ takes the form

$$D = \sum_{i=1}^{N^2-m} d_i |\chi_i\rangle\langle\chi_i| - \sum_{i=N^2-m+1}^{N^2} d_i |\chi_i\rangle\langle\chi_i|.$$  \hfill (7.1)

In analogy to the Kraus form [42, 43] we may write the canonical form of a not completely positive map

$$\rho' = \sum_{i=1}^{N^2-m} d_i \chi^{(i)}(\chi^{(i)})^\dagger - \sum_{i=N^2-m+1}^{N^2} d_i \chi^{(i)}(\chi^{(i)})^\dagger,$$  \hfill (7.2)

where the Kraus operators $A_i = \sqrt{d_i} \chi^{(i)}$ form an orthonormal basis. The above form suggests that a positive map may be represented as a difference of two completely positive maps [92]. Even though this statement is correct (for finite $N$), it does not solve the entire problem: taking any two CP maps and constructing a quasi-mixture (with negative weights allowed), $\Phi = (1+a)|\Psi_1\rangle\langle\Psi_1|^\text{CP} - a|\Psi_2\rangle\langle\Psi_2|^\text{CP}$, we do not know in advance how large the contribution $a$ of the negative part might be, to keep the map $\Phi$ positive. As a recently proposed technique of extending the system (and the map) a certain number of times is shown to give a constructive test for positivity for a...
large class of maps \[24\]. In fact the characterization of the set \(\mathcal{P}_N\) of positive maps: \(\mathcal{M}^{(N)} \rightarrow \mathcal{M}^{(N)}\) is by far not simple and remains a subject of considerable mathematical interest \[18, 21, 23, 56, 61, 62, 71, 79, 91, 95, 96, 108, 109\]. By definition, \(\mathcal{P}_N\) contains the set \(\mathcal{CP}_N\) of all CP maps as its proper subset.

To learn more about the set of positive maps we will need some other features of the operation of transposition \(T\). For any operation \(\Phi\) the modifications of the dynamical matrix induced by a composition with \(T\) may be described by the partial transpose transformation

\[
L_T\Phi = L^R_{\Phi}, \quad D_T\Phi = D^R_{\Phi}, \quad \text{and} \quad L_{\Phi T} = L^R_{\Phi}, \quad D_{\Phi T} = D^R_{\Phi}.
\]

(7.3)

To demonstrate this it is enough to use the explicit form of \(L_T\) and the following law of composition of dynamical matrices. Since the composition of two maps \(\Psi\Phi\) results in the product of linear matrices,

\[
L_{\Psi \Phi} = L_{\Psi} L_{\Phi}, \quad \text{hence} \quad D_{\Psi \Phi} = \left[D^R_{\Psi} D^R_{\Phi}\right]^R.
\]

(7.4)

Even though the composition of two maps is usually written as \(\Psi \cdot \Phi\), to simplify the notation the symbol \(\cdot\) will often be dropped. Note that both operations commute, \(\Psi \Phi = \Phi \Psi\), if \(\left[D^R_{\Phi}, D^R_{\Psi}\right] = 0\).

Positivity of \(D_{\Psi \Phi}\) follows also from the fact that the composition of two CP maps is completely positive. Alternatively one may prove the following reshuffling lemma

\[\text{Consider two Hermitian matrices } A \text{ and } B \text{ of the same size } K N.\]

If \(A \geq 0 \text{ and } B \geq 0\) then \((A^R B^R)^R \geq 0\).

(7.5)

It was formulated in a different set up and proved in \[36\].

The sandwiching of \(\Phi\) between two actions of transpositions does not influence the spectrum of the dynamical matrix, \(L_{T\Phi T} = L^R_{\Phi}\) and \(D_{T\Phi T} = D^R_{\Phi}\). Thus if \(\Phi\) is a CP map, so is \(T\Phi T\), (if \(D_{\Phi}\) is positive so is \(D^R_{\Phi}\)) – see Fig. 5.

![Fig. 5: a) Sketch of the set of CP maps and of its image with respect to transposition: the set of CcP maps, b) the isomorphic sets of quantum states (dynamical matrices) and its image under the action of partial transposition.](image)

The non completely positive map \(T\) of transposition allows one to introduce the following definition \[15, 21, 91\]: A map \(\Phi\) is called completely co-positive (CcP), if the map \(T\Phi\) is CP.

Properties \[63\] of the dynamical matrix imply that the map \(\Phi T\) could be used instead to define the same set of CcP maps. Thus any CcP map may be written in a Kraus–like form

\[
\rho' = \sum_{i=1}^{k} A_i \rho A_i^T.
\]

(7.6)

Moreover, as shown in Fig. 5 the set CcP may be understood as the image of CP with respect to the transposition. Since we have already identified the transposition with a kind of reflection, it is rather intuitive to observe that the set CcP is a twin copy of CP with the same shape and volume. This property is easiest to analyze for the set \(B_2\) of one qubit bistochastic maps \[77\]. The dual set of CcP unital one qubit maps, \(T(B_2)\), forms a tetrahedron spanned by four maps \(T\sigma_i\) for \(i = 0, 1, 2, 3\), which is the reflection of the set of the bistochastic maps with respect to the center of the tetrahedron - the completely depolarizing channel \(\Phi^*\) - see Fig. 5. Observe that the corners of \(B_2\) are formed by proper rotations, for which \(\det(t) = \eta_1 \eta_2 \eta_3\) is equal to \(+1\), while the extremal points of the set of CcP maps represent reflections for which \(\det(t) = -1\).
A positive map $\Phi$ is called \textit{decomposable}, if it may be expressed as a convex combination of a CP map and a CcP map, $\Phi = a\Phi_{\text{CP}} + (1 - a)\Phi_{\text{CcP}}$ with $a \in [0, 1]$. A relation between CP maps acting on quaternion matrices and the decomposable maps defined on complex matrices was shown by Kossakowski \cite{56}. An important characterization of the set $\mathcal{P}_2$ of positive maps acting on (complex) states of one qubit follows from the Størmer–Woronowicz theorem \cite{91, 108}.

\textit{Every one-qubit positive map $\Psi \in \mathcal{P}_2$ is decomposable.}

In other words, the entire set of one qubit positive maps can be represented by the convex hull of the set of CP and CcP maps,

$$\mathcal{P}_N = \text{conv hull}(\mathcal{CP}_N \cup \mathcal{CcP}_N)$$

for the sets $\mathcal{P}_N$ with $N \geq 3$. Consider a map defined on $\mathcal{M}(3)$, depending on three non-negative parameters,

$$\Psi_{a,b,c}(\rho) = \begin{bmatrix} a\rho_{11} + b\rho_{22} + c\rho_{33} & 0 & 0 \\ 0 & c\rho_{11} + a\rho_{22} + b\rho_{33} & 0 \\ 0 & 0 & b\rho_{11} + c\rho_{22} + a\rho_{33} \end{bmatrix} - \rho.$$  \hfill (7.7)

The map $\Psi_{2,0,2} \in \mathcal{P}_3$ was a first example of an indecomposable map found by Choi in 1975 \cite{20} in connection with positive biquadratic forms. As denoted schematically in Fig. 6, this map is extremal and belongs to the boundary of the convex set $\mathcal{P}_3$. The Choi map was generalized later in \cite{22} and in \cite{17}, where it was shown that the map (7.7) is positive if and only if

$$a \geq 1, \quad a + b + c \geq 3, \quad 1 \leq a \leq 2 \implies bc \geq (2 - a)^2,$$  \hfill (7.8)

while it is decomposable if and only if

$$a \geq 1, \quad 1 \leq a \leq 3 \implies bc \geq (3 - a)^2 / 4.$$  \hfill (7.9)

In particular, $\Psi_{2,0,c}$ is positive but not decomposable for $c \geq 1$. All generalized indecomposable Choi maps are known to be atomic \cite{33}, it is they cannot be written as a convex sum of 2–positive and 2–co–positive maps \cite{97}. An example of an indecomposable map belonging to $\mathcal{P}_4$ was given by Robertson \cite{86}. A family of indecomposable maps for an arbitrary finite dimension $N \geq 3$ was recently found by Kossakowski \cite{57}. They consist of an affine contraction of the set $\mathcal{M}(N)$ of density matrices into the ball inscribed in it followed by a generic rotation from $O(N^2 - 1)$. Although several other methods of construction of indecomposable maps were proposed \cite{51, 78, 97, 98}, some of them in the context of quantum entanglement \cite{34, 100, 110}, the general problem of describing all positive maps remains open. In particular, it is not known, if one could find a finite set of $K$ positive maps $\{\Psi_j\}$, such that

$$\mathcal{P}_N = \text{conv hull}\left(\bigcup_{j=1}^{K} \Psi_j(\mathcal{CP}_N)\right).$$

Due to the theorem of Størmer and Woronowicz the answer is known only for $N = 2$, for which $K = 2$, $\Psi_1 = \mathbb{I}$ and $\Psi_2 = T$. As emphasized by Horodeccy in an important work \cite{93}, these properties of the set $\mathcal{P}_N$ become decisive for the separability problem: the separability criterion based on the positivity of ($\mathbb{I} \otimes T)\rho$ works for the system of two qubits, but does not solve the problem in the general case of the $N \times N$ composite system.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig6.png}
\caption{Sketch of the set positive maps: a) for $N = 2$ all maps are decomposable, b) for $N > 2$ there exist non-decomposable maps.}
\end{figure}

The indecomposable maps are worth investigating, since each such map provides a criterion for separability. Conditions for a positive map $\Phi$ to be decomposable were found some time ago by Størmer \cite{92}. Since this criterion is
not a constructive one, we describe here a simple test which may confirm the decomposability. Assume first that the map is not symmetric with respect to the transposition \( \Phi \neq T\Phi \). These two different points determine a line in the space of maps, parametrized by \( \beta \), along which we analyze the dynamical matrix

\[
D_{\beta\Phi + (1-\beta)T\Phi} = \beta D_{\Phi} + (1-\beta)D_{\Phi}^T, 
\]

(7.10)

and check its positivity by diagonalization. Assume that this matrix is found to be positive for some \( \beta_* < 0 \) (or \( \beta_* > 1 \)), then the line (7.10) crosses the set of completely positive maps (see Fig. 7). Since \( D(\beta_*) \) represents a CP map \( \Psi_{CP} \), hence \( D(1-\beta_*) \) defines the set of completely positive maps (see Fig. 7). Since the reshuffling of a matrix does not influence its HS norm of the difference between the superoperators, \( d(\Psi, \Phi) = d_{HS}(L_{\Phi}, L_{\Phi}) = ||L_{\Phi} - L_{\Phi}||_{HS} \). Since the reshuffling of a matrix does not influence its HS norm, the distance can be measured directly in the space of dynamical matrices, \( d(\Psi, \Phi) = d_{HS}(D_{\Phi}, D_{\Phi}) \). Note that for unital one qubit maps, (6.4) with \( \vec{\kappa} = 0 \), one has \( d(\Phi_1, \Phi_2) = |\vec{n}_1 - \vec{n}_2| \), so Fig. 3 represents correctly the HS geometry of the space of \( N = 2 \) unital maps.

In order to characterize, to what extent a given map \( \Psi \) acting on \( M^{(N)} \) is close to the boundary of the set of positive (CP or CcP) maps, let us introduce the following quantities

a) complete positivity, \( cp(\Phi) \equiv \min_{M^{(N)}} \langle \rho | D_{\Phi} | \rho \rangle \),

(7.11)

b) complete co–positivity, \( ccp(\Phi) \equiv \min_{M^{(N)}} \langle \rho | D_{\Phi}^T | \rho \rangle \),

(7.12)

c) positivity, \( p(\Phi) \equiv \min_{x,y \in CP^{N-1}} [\langle x \otimes y | D_{\Phi} | x \otimes y \rangle] \).

(7.13)

The two first quantities may be easily found by diagonalization, \( cp(\Phi) = \min \{ \text{eig}(D_{\Phi}) \} \) and \( ccp(\Phi) = \min \{ \text{eig}(D_{\Phi}^T) \} \). Although \( p(\Phi) \geq cp(\Phi) \) by construction the evaluation of positivity is more involved, since one needs to perform the minimization over the space of all product states, i.e. the Cartesian product \( CP^{N-1} \times CP^{N-1} \). No straightforward method of computing this minimum is known, so one has to rely on numerical minimization. In certain cases this quantity was estimated analytically by Terhal \cite{100} and numerically by Gülne et al. \cite{31, 32} in the context of characterizing the entanglement witnesses. In fact a non–positive dynamical matrix \( D \), which describes a non completely positive map, may be just considered as an entanglement witnesses – an operator \( D \) such \( \text{Tr} D\rho \) is not negative for all separable states and negative for a given entangled state \( \rho \).

As follows from the positivity of \( D \) and \( D^T \) and the property of block positivity (4.7), a given map \( \Phi \) is completely positive (CcP, positive) if and only if the complete positivity (cp, positivity) is non–negative. As marked in Fig. 6, the relation \( cp(\Phi) = 0 \) defines the boundary of the set \( CP_N \), while \( ccp(\Phi) = 0 \) and \( p(\Phi) = 0 \) define the boundaries of \( CcP_N \) and \( P_N \). By direct diagonalization of the dynamical matrix we find that \( cp(1) = ccp(T) = 0 \) and \( ccp(1) = cp(T) = -1 \).

For any not completely positive map \( \Phi_{CP} \) one may look for its best approximation with a physically realizable CP map \( \Phi_{CP} \), e.g. by minimizing their HS distance \( d(\Phi_{CP}, \Phi_{CP}) \) – see Fig. 6. Such maps, called structural physical approximation were introduced in \cite{42} to propose an experimentally feasible scheme of entanglement detection and later studied in \cite{23}.

To see a simple application of complete positivity, consider a non physical positive map with \( cp(\Phi_{CP}) = -x < 0 \). Its possible CP approximation, but generally not the optimal one, may be constructed out of its convex combination.
with the completely depolarizing channel $\Phi_*$. Diagonalizing the dynamical matrix representing the map $\Psi_* = a\Phi_{n\text{CP}} + (1-a)\Psi_*$ with $a = 1/(N x + 1)$ we see that its smallest eigenvalue is equal to zero, so $\Psi_*$ belongs to the boundary of $\mathcal{CP}_N$. Hence the distance $d(\Phi_{n\text{CP}}, \Phi_*)$, which is a function of the complete positivity $cp(\Phi_{n\text{CP}})$, gives an upper bound for the distance of $\Phi_{n\text{CP}}$ from the set $\mathcal{CP}$. In a similar way one may use $ccP(\Phi)$ to obtain an upper bound for the distance of an analyzed non $CcP$ map $\Phi_{nCcP}$ from the set $CcP$. Interestingly, the solution of the analogous problem in the space of density matrices allows one to characterize the entanglement of a two-qubit mixed state $\rho_1$ by its minimal distance to the set of separable states. In the two-qubit system the entangled states do not have positive partial transpose, so $T_A(\rho_1)$ is not a state. As shown in Fig. 9b one may also study a related problem of finding the state $\rho_2$ which is closest to $T_A(\rho_1)$.

VIII. JAMIOLKOWSKI ISOMORPHISM

Let $\mathcal{CP}_N$ denote the space of all trace preserving, completely positive maps $\Phi : \mathcal{M}^{(N)} \rightarrow \mathcal{M}^{(N)}$. Note that this is a convex set. Any such a map $\Phi$ may be uniquely represented by its dynamical matrix $D_\Phi$ of size $N^2$. It is a positive, Hermitian matrix and its trace is equal to $N$. Hence the rescaled matrix $\rho_\Phi \equiv D_\Phi/N$ represents a mixed state in $\mathcal{M}^{(N^2)}$, and the entropy of the operation $S(\Phi)$ equals to the von Neumann entropy of $\rho_\Phi$. In fact rescaled dynamical matrices explore only a subspace of this set determined by the trace preserving conditions (13), which impose $N^2$ constraints. Let us denote this $N^4 - N^2$ dimensional set by $\mathcal{M}_I^{(N^2)}$. Since for any trace preserving CP map we may find a dynamical matrix, and vice versa, the correspondence between the maps from $\mathcal{CP}_N$ and the states of $\mathcal{M}_I^{(N^2)}$ is one–to–one. In Table V this isomorphism is labeled by $J_{III}$.

Let us find the dynamical matrix for the identity operator, $L = I_{N^2}$,

$$L_{nm}^{1} = \delta_{mn} \delta_{\mu \nu}, \quad \text{so that} \quad D_{nm}^{1} = (L_{nm}^{1})^R = \delta_{\mu \nu} \delta_{mn} = N \rho_\psi^{\psi_{\nu}}_{n \mu}.$$  

where $\rho_\psi = |\psi\rangle \langle \psi|$ represents the operator of projection on the maximally entangled state of the composite system

$$|\psi\rangle = \sum_{i=1}^{N} \frac{1}{\sqrt{N}} |i\rangle \otimes |i\rangle.$$  

TABLE V: Jamiołkowski Isomorphism between Hermiticity reserving linear maps $\Phi$ deﬁned on the space of mixed states $\mathcal{M}^{(N)}$ which act on $\mathcal{H}_N$ and the operators $D_\Phi$ on the composed space $\mathcal{H}_N \otimes \mathcal{H}_N$.

| Isomorphism | Linear maps $\Phi : \mathcal{M}^{(N)} \rightarrow \mathcal{M}^{(N)}$ | Hermitian operators $D_\Phi : \mathcal{H}_{N^2} \rightarrow \mathcal{H}_{N^2}$ |
|-------------|---------------------------------------------------------------|---------------------------------|
| $J_I$       | positive maps $\Phi$                                          | positive operators $D_\Phi$     |
| $J_{III}$   | completely positive maps $\Phi$                              | states $\rho = D/N$ such that $Tr_\Phi D = I$ |
| $J_{IIIa}$  | quantum operations: CP, trace preserving maps                 | states $\rho = D/N$ such that $Tr_\Phi D = I$ |
| $J_{IVA}$   | completely positive, unital maps                             | mixed states $\rho = D/N$ with positive partial transpose |
| example of $J_{IVA}$ for $N = 2$ | CP and CcP trace preserving maps | separable states $\rho = D/N$ of a $2 \times 2$ composite system |
| $J_{IVA}$   | unitary rotations                                            | maximally entangled states $(U \otimes 1)|\psi\rangle\langle 1| $ |
| $N = 2$ example of $J_{IVA}$ Pauli matrices versus Bell states $\rho_0 = |\phi\rangle\langle \phi|$ | $\rho' = U \rho U^\dagger$, $D_{\Phi} = (U \otimes U^\dagger)^R$ | pure states $\langle \rho \rangle$ |
| $J_V$       | completely depolarizing channel $\Phi_*$                     | maximally mixed state $\rho_* = I/N$ |

Let us denote this $N^4 - N^2$ dimensional set by $\mathcal{M}_I^{(N^2)}$. Since for any trace preserving CP map we may find a dynamical matrix, and vice versa, the correspondence between the maps from $\mathcal{CP}_N$ and the states of $\mathcal{M}_I^{(N^2)}$ is one–to–one. In Table V this isomorphism is labeled by $J_{III}$.
This state is written in its Schmidt form \( |\psi\rangle\langle\psi| \) (for \( N = 2 \) it is the famous Bell state), and we see that all its Schmidt coefficients are equal, \( \lambda_1 = \lambda_2 = \lambda_N = 1/N \). Thus we have found that the identity operator corresponds to the maximally entangled pure state \( |\psi\rangle\langle\psi| \) of the composite system. Interestingly, this correspondence may be extended for other operations, or in general, for arbitrary linear maps. Any linear map \( \Phi \) acting on the space of mixed states \( \mathcal{M}^{(N)} \) can be associated, via its dynamical matrix \( D_\Phi \), with an operator acting in the enlarged Hilbert state \( \mathcal{H}_N \otimes \mathcal{H}_N \)\( \Phi : \mathcal{M}^{(N)} \rightarrow \mathcal{M}^{(N)} \)

\[
D_\Phi = N [\Phi \otimes \mathbb{I}](|\psi\rangle\langle\psi|) \quad (8.3)
\]

To show this we represent the linear map \( \Phi \) by its matrix \( L \) introduced in (7.1), write the operator \( \Phi \otimes \mathbb{I} \) as an eight–indices matrix and study its action on the state \( \rho^\psi \) expressed by (5.1),

\[
L_{m'n''\mu'\nu'} N \rho_{m'n'\mu'n'n'} = L_{m'n''\mu'\nu'} = D_{m'n''\mu'\nu'}. \quad (8.4)
\]

An analogous operation \( \mathbb{I} \otimes \Phi \) acting on \( \rho^\psi \) leads to the matrix \( D^F \) with the same spectrum. Conversely, for any positive matrix \( D \) we find the corresponding map \( \Phi \) by diagonalization. The reshaped eigenvectors \( |\lambda_i\rangle \) of \( D \), rescaled by the roots of its eigenvalues give the canonical Kraus form (4.9, 4.13) of the corresponding operation \( \Phi \). Furthermore, the entropy of the quantum operation \( S(\Phi) \) equals the von Neumann entropy \( S(\rho_\Phi) \) of the corresponding state \( \rho_\Phi = D_\Phi /N \).

Consider now a more general case in which \( \rho \) denotes a state acting on a composite Hilbert space \( \mathcal{H}_N \otimes \mathcal{H}_N \). Let \( \Phi \) be an arbitrary map which sends \( \mathcal{M}^{(N)} \) into itself and let \( D_\Phi = L_\Phi^R \) denote its dynamical matrix (of size \( N^2 \)). Acting with the extended map on \( \rho \) we find its image \( \rho' = [\Phi \otimes \mathbb{I}](\rho) \). Writing down the explicit form of the corresponding linear map in analogy to (8.5), and contracting over the four indices representing \( \mathbb{I} \), we obtain

\[
(\rho')^R = L_\Phi \rho^R \quad \text{so that} \quad \rho' = (D_\Phi^R \rho^R)^R. \quad (8.5)
\]

In the above formula the standard multiplication of square matrices takes place, in contrast to Eq. (8.4) in which the state \( \rho \) acts on a simple Hilbert space and is treated as a vector.

Note that Eq. (8.5) may be obtained as a special case of (8.3) if one takes for \( \rho \) the maximally entangled state (8.2), for which \( (\rho^\psi)^R = \mathbb{I} \). Formula (8.3) provides a useful application of the dynamical matrix corresponding to a map \( \Phi \) acting on a subsystem. Since the normalization of matrices does not influence positivity, this result implies the reshuffling lemma (7.5).

Formula (8.3) may also be used to find operators \( D \) associated with positive maps \( \Phi \) which are neither trace preserving nor complete positive. The correspondence between the set of positive linear maps and dynamical matrices acting in the composite space and positive on product states is called Jamiołkowski isomorphism since it follows from his results obtained in (8.1). Some aspects of the duality between maps and states were recently investigated in (8.1). Let us mention here explicitly certain special cases of this isomorphism labeled by \( J_1 \) in Table (8.1). The set of all completely positive maps \( \Phi \) is isomorphic to the set of all positive matrices \( D \), (case \( J_{11} \)). Unitary CP maps are related to dynamical matrices which satisfy \( \text{tr}_B D = 1 \) (case \( J_{11} \)). The set of all quantum operation, (i.e. the trace preserving, CP maps) corresponds to the set of positive matrices \( D \) fulfilling another constraint, \( \text{tr}_A D = 1 \) – see Table (8.1) item \( J_{11} \). An apparent asymmetry between the role of both subsystems is due to the particular choice of the relation (8.4) if the operator \( \mathbb{I} \otimes \Phi \) is used instead, the subsystems \( A \) and \( B \) in the partial trace constraints need to be interchanged.

An important case \( J_{IV} \) of the isomorphism concerns the states with positive partial transpose, \( \rho^{TT_A} \geq 0 \), called briefly PPT states. Another case, \( J_{IV:a} \), relates the set of unitary rotations, \( \rho' = \Phi(\rho) = U \rho U \dagger \) with the maximally entangled states, \( (U \otimes \mathbb{I}) |\psi\rangle\langle\psi| \). The local unitary operation \( (U \otimes \mathbb{I}) \) preserves the purity of a state and its Schmidt coefficients. Thus the set of unitary matrices \( U \) of size \( N \) is isomorphic to the set of the maximally entangled pure states of the composite \( N \times N \) system. In particular, vectors obtained by reshaping the Pauli matrices \( \sigma_j \) represent the Bell states in the computational basis, as listed in Table (8.1). Eventually, case \( J_V \) consists of a single, distinguished
IX. QUANTUM MAPS AND QUANTUM STATES

Relation (8.3) allows one to link an arbitrary linear map \( \Phi \) with the corresponding linear operators given by the dynamical matrix \( D_\Phi \). Expressing the maximally entangled state \( |\psi\rangle \) in (8.3) by its Schmidt form (8.2) we may compute the matrix elements of \( D_\Phi \) in the product basis consisting of the states \( |i \otimes j\rangle \). Due to the factorization of the right hand side we see that the double sum describing \( \rho_\Phi = D_\Phi /N \) drops out and the result reads

\[
\langle k \otimes i | D_\Phi | l \otimes j \rangle = \langle k | \Phi(|i\rangle \langle j|) | l \rangle.
\]

This equation may also be understood as a definition of a map \( \Phi \) related to the linear operator \( D_\Phi \). It proves the isomorphism \( J_I \) from Table VIII if \( D_\Phi \) is block positive, then the corresponding map \( \Phi \) sends positive operators into positive operators [48]. As listed in Table VIII and shown in Fig. 9 the Jamiołkowski isomorphism (9.1) may be applied in various setups [8]. Relating linear maps from \( P_N \) with the operators acting on an extended space \( \mathcal{H}_N \otimes \mathcal{H}_N \) we may compare:

i) individual objects, e.g. completely depolarizing channel \( \Phi_* \) and the maximally mixed state \( \rho_* \),

ii) families of objects, e.g. the depolarizing channels and the Werner states [105],

iii) entire sets, e.g. the set of \( CP \cup CcP \) maps and the set of PPT states,

iv) certain problems, e.g. for an arbitrary \( CP \) map \( \Phi \) find the closest \( CcP \) map, and the problem of finding the PPT state (separable state for \( N = 2 \)) closest to an arbitrary (entangled) state, and

v) their solutions...

To get some more experience concerning the analyzed duality between quantum maps and quantum states compare both sides of Fig. 9. Note that this illustration may also be considered as a strict representation of a fragment of the space of one-qubit unital maps (a) or the space of two-qubits density matrices in the HS geometry (b). It is nothing else but the cross-section of the cube representing the positive maps in Fig. 3 along the plane determined by \( 1, T \) and \( \Phi_* \).

![FIG. 9: Isomorphism between objects, sets, and problems: a) linear one qubit maps, b) linear operators acting in two-qubit Hilbert space \( \mathcal{H}_4 \). Labels \( J_i \) refer to the sets related by the isomorphisms defined in Table VIII.](image)

Let us finish this section by pointing out an analogue of the Jamiołkowski isomorphism in the classical case. The space of all classical states – probability vectors of size \( N \) – forms the \( N - 1 \) dimensional simplex \( \Delta_{N-1} \). A discrete dynamics in this space is given by a stochastic transition matrix \( T_N : \Delta_{N-1} \rightarrow \Delta_{N-1} \). It contains non-negative entries, and due to stochasticity the sum of all its elements is equal to \( N \). Hence reshaping the transition matrix \( T_N \) and rescaling it by \( 1/N \) we receive a probability vector \( \vec{r} \) of length \( N^2 \). The classical states defined in this way form a measure zero, \( N(N-1) \) dimensional, convex subset of \( \Delta_{N^2 -1} \). Consider, for instance, the set of \( N = 2 \) stochastic matrices, which can be parametrized as \( T_2 = \begin{bmatrix} a & b \\ 1-a & 1-b \end{bmatrix} \) with \( a, b \in [0, 1] \). The set of the corresponding
probability vectors $\vec{t} = (a, b, 1 - a, 1 - b)/2$ forms a square of size $1/2$ – the maximal square which may be inscribed into the unit tetrahedron $\Delta_3$ of all $N = 4$ probability vectors.

The classical dynamics may be considered as a (very) special subclass of quantum dynamics, defined on the set of diagonal density matrices. Hence the classical and quantum duality between maps and states may be succinctly summarized in the following, commutative diagram

$$\begin{align*}
\text{quantum :} & \quad [\Phi : \mathcal{M}(N) \to \mathcal{M}(N)] \quad \mapsto \quad D_\Phi \in \mathcal{M}(N^2) \\
\downarrow \text{ maps} & \quad \downarrow \text{ states} \\
\text{classical :} & \quad [T : \Delta_{N-1} \to \Delta_{N-1}] \quad \mapsto \quad \vec{t} \in \Delta_{N^2-1}.
\end{align*}$$

Alternatively, vertical arrows may be interpreted as the action of the coarse graining operation $\Psi_{CG}$ defined in section V. For instance, for the trivial (do nothing) one–qubit quantum map $\Phi_1$, the superoperator $L = \mathbb{I}_4$ restricted to diagonal matrices gives the identity matrix, $T = \mathbb{I}_2$, and the classical state $\vec{t} = (1, 0, 0, 1)/2 \in \Delta_3$. On the other hand, this very vector represents the diagonal of the maximally entangled state $\frac{1}{2} D_\Phi = |\psi\rangle\langle\psi|$. To prove the commutativity of the diagram (9.2) in the general case define the stochastic matrix $T$ as a submatrix of the superoperator (4.3), $T_{mn} = L_{mm}$ (left vertical arrow). Note that the vector $\vec{t}$ obtained by its reshaping satisfies $\vec{t} = \text{diag}(L^R) = \text{diag}(D_\Phi)$, so it represents the diagonal of the dynamical matrix (right arrow).

X. ENVOI

In this work we analyzed the space $\mathcal{P}_N$ of positive maps, which send the set of mixed quantum states $\mathcal{M}(N)$ into itself, and its various subsets: the set $\mathcal{CP}_N$ of completely positive maps, and the set $\mathcal{B}_N$ of bistochastic maps. For any quantum map $\Psi$ we have introduced three quantities, (7.11 –7.13), to characterize the location of $\Psi$ with respect to itself, and its various subsets: the set $\mathcal{B}_N$ of all bistochastic maps. For instance, for the trivial (do nothing) one–qubit quantum map $\Phi$, the known structure of the set of completely positive maps relates to the structure of all quantum states, while the description of the (larger) set of all positive maps would allow us to describe the subset of all separable states.

It is a pleasure to thank R. Alicki, R. Dobrzański–Denkowitz, T. Havel, P. Horodecki, R. Horodecki, A. Kossakowski, M. Kuś, W. A. Majewski and F. Mintert for fruitful discussions and helpful comments. Financial support by Komitet Badań Naukowych under the grant PBZ-Min-008/P03/03 and Swedish grant from VR is gratefully acknowledged.
