DISCRIMINATION OF POVMS WITH RANK-ONE EFFECTS

ALEKSANDRA KRAWIEC\textsuperscript{1,*}, LUKASZ PAWELA\textsuperscript{1}, AND ZBIGNIEW PUCHALA\textsuperscript{1,2}

Abstract. The main goal of this work is to provide an insight into the problem of discrimination of positive operator valued measures with rank-one effects. It is our intention to study multiple shot discrimination of such measurements, that is the case when we are able to use to unknown measurement a given number of times. Furthermore, we are interested in comparing two possible discrimination schemes: the parallel and adaptive ones. To this end we construct a pair of symmetric, information complete positive operator valued measures which can be perfectly discriminated in a two-shot adaptive scheme. On top of this we provide an explicit algorithm which allows us to find this adaptive scheme.

1. Introduction

The transformation of quantum states is at the core of quantum computing. The most general mathematical tool describing how quantum states transform are quantum channels. While performing computation, one would like to certify that the operation in use agrees with the one given by the classical description. The discrimination task is closely related to the hypothesis testing. This is one of the reasons why the problem of discrimination of quantum channels has attracted a lot of attention [1–4].

Various approaches have been utilized to study the distinguishability of quantum channels. In work [5] the authors introduced the resource theory of asymmetric distinguishability for quantum channels which was further developed in [6]. A novel scenario called coherent quantum channel discrimination was studied in [7]. Interesting results on the distinguishability concern specific classes of quantum channels like unitary [8,9] and Pauli [10] channels.

We can consider two approaches to channel discrimination – a parallel and an adaptive scheme. In the former, we are allowed to perform the unknown channel a fixed, finite, number of times on an input state, while in the latter case we can also perform additional operations between the applications of the unknown channel. In general it is a nontrivial question which discrimination scheme should be used to distinguish between two quantum channels. It seems natural that the use of adaptive scheme should improve

the discrimination. However, it may happen that it suffices to use the parallel one. For example in the case of unitary channels \[8,9\] and von Neumann measurements it was shown in \[11,13\] that the parallel scheme is always optimal. It is also known that asymptotically the use of adaptive strategy does not give an advantage over the parallel one for the discrimination of classical \[14\] and classical-quantum channels \[15\]. Nevertheless, an example of a pair of quantum channels that cannot be distinguished perfectly in parallel but can be distinguished by the adaptive scheme was proposed in \[16\]. These channels are however pretty artificial. We will give another, natural example of two channels which have this property. These channels are two symmetric informationally complete positive operator valued measures (SIC POVMs) \[17,18\] of dimension three. Moreover, we will show that there exist many pairs of channels which can be distinguished only adaptively and present numerical results for the discrimination of random symmetric operator valued measures (POVMs).

In this work we focus on the following scheme. There are two measurements \(P_1\) and \(P_2\). One of them is secretly chosen (with probability \(\frac{1}{2}\)) and put into a black box. The black box containing the unknown measurement device can be used any finite number of times in any configuration. Two schemes of multiple-shot discrimination will be studied: parallel and adaptive. The parallel scheme does not require any processing between the uses of the black box \[19\]. In the adaptive scheme, however, the processing between the uses of the black box plays a crucial role. We can prepare any input state and put it through the discrimination network. Finally, we perform a known measurement and make a decision which measurement was put into the black box.

This work is organized as follows. We begin with preliminaries in Section 2. The conditions allowing for perfect discrimination in both parallel and adaptive scenarios are stated in Section 3. The example of qutrit SIC POVMs which can be discriminated perfectly only by the adaptive scheme, as well as the algorithm allowing for perfect discrimination, are presented in Section 4. Eventually, in Section 5 one can find numerical results for the discrimination of random rank-one POVMs.

2. Preliminaries

Let \(\mathcal{X}\) and \(\mathcal{Y}\) be finite-dimensional complex Hilbert spaces. We denote by \(L(\mathcal{X},\mathcal{Y})\) the set of linear operators \(A : \mathcal{X} \to \mathcal{Y}\) and write shortly \(L(\mathcal{X})\) for \(L(\mathcal{X},\mathcal{X})\). We will use the notation \(U(\mathcal{X},\mathcal{Y})\) for the set of isometry operators and \(U(\mathcal{X})\) for the set of unitary operators. A set of quantum states will be denoted \(D(\mathcal{X})\). Quantum operations \(\Phi : L(\mathcal{X}) \to L(\mathcal{Y})\) will be denoted \(T(\mathcal{X},\mathcal{Y})\) while the subset of quantum channels will be denoted \(C(\mathcal{X},\mathcal{Y})\).

We will need the notion of vectorization of a matrix. For the identity operator \(1\) of the space \(L(\mathcal{X})\) we define its vectorization as \([1] = \sum_i |i\rangle\). It can be generalized to an arbitrary matrix \(X \in L(\mathcal{X})\) as \([X] = (X \otimes 1)|1\rangle\).

The most general form of quantum measurements are positive operator valued measures (POVMs). Formally, a collection of positive semidefinite operators \(P = \{E_1, \ldots, E_m\} \subset L(\mathcal{X})\) is called a POVM if \(\sum_{i=1}^m E_i = 1\). The operators \(E_i\) are called effects. Every quantum measurement \(P = \)
\{E_1, \ldots, E_m\} can be identified with a quantum channel which gives a classical output. Its action on a quantum state \( \rho \) can be written as

\[
P(\rho) = \sum_{i=1}^{m} \text{Tr}(E_i \rho) |i\rangle \langle i|.
\]

Let us for a moment focus on the distinguishability of general quantum channels. This problem has been widely studied in the literature in various settings and utilizing a plethora of mathematical tools \[20, 21\]. The probability of correct discrimination between channels \( \Phi, \Psi \in \mathcal{C}(X, Y) \) is upper-bounded by the Holevo-Helstrom theorem \[22\]

\[
p \leq \frac{1}{2} + \frac{1}{4} \| \Phi - \Psi \|_\Diamond.
\]

The diamond norm, known also as the completely bounded trace norm, \( \| \cdot \|_\Diamond \) is defined for a Hermiticity-preserving linear map \( \Phi \in \mathcal{T}(X, Y) \) as

\[
\| \Phi \|_\Diamond = \max_{\| X \|_1 = 1} \| (\Phi \otimes I_L(X)) (X) \|_1.
\]

where \( \| X \|_1 \) is defined as a sum of singular values of \( X \). The above-mentioned bound describes the situation when the black box containing the unknown POVM can be used only once. Therefore \( \Phi \) and \( \Psi \) are said to be perfectly distinguishable in a single-shot scenario iff \( \| \Phi - \Psi \|_\Diamond = 2 \).

2.1. Parallel discrimination. The approach introduced by Holevo-Helstrom theorem can be easily generalized into the parallel discrimination scheme. Is such a case the probability of correct discrimination after \( N \) uses of the black box is upper-bounded by

\[
p \leq \frac{1}{2} + \frac{1}{4} \| \Phi^\otimes N - \Psi^\otimes N \|_\Diamond.
\]

The parallel discrimination scheme is depicted in Figure 1. Black boxes containing the unknown POVM are denoted by question marks. As an input state we use the state on \( N + 1 \) registers denoted by \( |\psi_1, \ldots, N+1\rangle \). After performing the unknown POVM on \( N \) registers we obtain classical outputs \( i_1, \ldots, i_N \). Using this classical information we prepare another known measurement and perform it on the last register. Basing on the last measurement’s outcome we make a decision which measurement was hidden in the black box.

![Figure 1. Parallel discrimination scheme](image-url)
will be presented in the subsequent section. Let $\mathcal{P}_1 = \{|x_1\rangle\langle x_1|, \ldots, |x_m\rangle\langle x_m|\}$ and $\mathcal{P}_2 = \{|y_1\rangle\langle y_1|, \ldots, |y_m\rangle\langle y_m|\}$ be POVMs for $m \geq d$. Then POVMs $\mathcal{P}_1$ and $\mathcal{P}_2$ have perfect parallel distinguishability if there exists an integer $N > 0$ and a quantum state $\rho \in \mathcal{D}(X^\otimes N)$ such that for all multi-indices $i_1, \ldots, i_N$ we have

\begin{equation}
\langle x_{i_1} \ldots x_{i_N} | \rho | y_{i_1} \ldots y_{i_N} \rangle = 0.
\end{equation}

2.2. Adaptive discrimination scheme. If we are allowed to perform processing between the uses of black boxes, then we arrive at the adaptive discrimination scheme which is depicted in Figure 2. Although the adaptive discrimination scheme can be used for any number of uses, $N$, of the black box, for the sake of clarity let us focus on the case $N = 3$. We prepare an input state $|\psi\rangle$ and perform the unknown POVM on the first register. Basing on the measurement’s outcome $i_1$ we perform a quantum channel $\Phi_{i_1}$ on the other registers. Later, we perform the unknown POVM on the second register and obtain the classical outcome $i_2$. Then we perform a channel $\Phi_{i_1,i_2}$ on the remaining registers which now depends on both $i_1$ and $i_2$. In what follows we perform the unknown POVM on the third register and obtain the outcome $i_3$. Finally, we perform the known measurement on the last register which now depends on all classical outcomes $i_1, i_2, i_3$ and make a decision which of the POVMs was hidden in the black box.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{adaptive_discrimination_scheme.png}
\caption{Adaptive discrimination scheme}
\end{figure}

3. Parallel vs adaptive discrimination scheme

In this section we will state the condition when a pair of quantum operations can be distinguished perfectly in the adaptive scheme while the parallel scheme does not allow for perfect discrimination. Before reviewing some known results on the distinguishability of general quantum operations, we need to introduce the notion of disjointness between quantum operations. Let $\rho \in \mathcal{D}(\mathcal{X})$ be a quantum state with spectral decomposition $\rho = \sum \lambda_i | \lambda_i \rangle \langle \lambda_i |$. Then we define its support as $\text{supp}(\rho) = \text{span}\{| \lambda_i \rangle : \lambda_i > 0\}$.

**Definition 1.** Two quantum states $\rho_1, \rho_2 \in \mathcal{D}(\mathcal{X})$ are called disjoint when

\begin{equation}
\text{supp}(\rho_1) \cap \text{supp}(\rho_2) = \{0\}.
\end{equation}

The notion of disjointness can be generalized to quantum operations. Thus, following [23], we have the following definition.

**Definition 2.** Two quantum operations $\Phi, \Psi \in T(\mathcal{X}, \mathcal{Y})$ are called (entanglement-assisted) disjoint if there exists an input state $|\psi\rangle \in \mathcal{X} \otimes Z$ such that $(\Phi \otimes \mathbb{I}_L(Z)) (|\psi\rangle \langle \psi|)$ and $(\Psi \otimes \mathbb{I}_L(Z)) (|\psi\rangle \langle \psi|)$ are disjoint.
Let $\Phi, \Psi \in T(\mathcal{X}, \mathcal{Y})$ be quantum operations with Kraus operators $\{E_i\}_i$ and $\{F_j\}_j$, respectively. From [23] we have a condition for perfect distinguishability by a finite number of uses given by the following theorem.

**Theorem 1.** Quantum operations $\Phi : \rho \mapsto \sum_i E_i \rho E_i^\dagger$ and $\Psi : \rho \mapsto \sum_j F_j \rho F_j^\dagger$ are perfectly distinguishable by a finite number of uses iff they are disjoint and $1 \notin \text{span}\{E_i^\dagger F_j\}_{i,j}$.

The following corollary comes from [19] and gives a condition when quantum operations cannot be distinguished in parallel.

**Corollary 1.** Using notation as in Theorem 1, if $\text{span}\{E_i^\dagger F_j\}_{i,j}$ contains a positive operator $\rho > 0$, then $\Phi$ and $\Psi$ cannot be distinguished perfectly in parallel by any finite number of uses.

Combining the above we obtain the corollary which states a condition when operations can be distinguished only by the adaptive scheme, that is when parallel discrimination is not sufficient but adaptive discrimination allows for perfect discrimination.

**Corollary 2.** Using notation as in Theorem 1, if $\text{span}\{E_i^\dagger F_j\}_{i,j}$ contains a positive operator $\rho > 0$, operations $\Phi$ and $\Psi$ are (entanglement-assisted) disjoint and $1 \notin \text{span}\{E_i^\dagger F_j\}_{i,j}$, then $\Phi$ and $\Psi$ can be distinguished perfectly only by the adaptive scheme.

Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be rank-one POVMs with effects $\{|i\rangle\langle i|\}_i$ and $\{|y_i\rangle\langle y_i|\}_i$, respectively. Therefore the Kraus operators of $\mathcal{P}_1$ and $\mathcal{P}_2$ can be chosen as $E_i = \{|i\rangle\langle x_i|\}_i$ and $F_i = \{|i\rangle\langle y_i|\}_i$ respectively. Hence in order to check whether $1 \notin \text{span}\{E_i^\dagger F_j\}_{i,j}$ it suffices to see whether $1 \notin \text{span}\{|i\rangle\langle y_i|\}_i$ as $E_i^\dagger F_j = |x_i\rangle\langle y_j|\delta_{ij}$.

4. SIC POVMs

In this section we give an example of a pair of quantum measurements for which the use of parallel discrimination scheme does not give perfect distinguishability but they can be distinguished perfectly by the adaptive scheme. Let us begin with a definition. A POVM $\mathcal{P} = \{E_1, \ldots, E_d^2\} \subset \mathcal{L}(\mathcal{X}_d)$ of dimension $d$ is called a SIC POVM if $E_i = \frac{1}{d} |\phi_i\rangle\langle \phi_i|$ and

\begin{equation}
|\langle \phi_i | \phi_j \rangle|^2 = \frac{1}{d+1}
\end{equation}

for every $i, j = 1, \ldots, d^2, i \neq j$. It is worth mentioning here that it is an open question whether SIC POVMs exist in all dimensions. So far numerical results are known for all dimensions up to 151 and for a few other dimensions up to 844 [24].

In what follows we will construct an example of a pair of quantum channels which cannot be distinguished perfectly in the parallel scheme but can be distinguished perfectly in the adaptive scheme. Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be qutrit SIC POVMs with effects $\{|x_i\rangle\langle x_i|\}_i$, where $|x_i\rangle = \frac{1}{\sqrt{3}} |\phi_i\rangle$, and $\{|y_i\rangle\langle y_i|\}_i$, respectively. Let $\pi = (9, 8, 7, 3, 1, 2, 6, 4, 5)$ be a permutation such that $|y_i\rangle = |x_{\pi(i)}\rangle$ for $i = 1, \ldots, 9$. A detailed construction of the POVM $\{|x_i\rangle\langle x_i|\}_i$ can be found in [25] and the exact form of the fiducial vector is stated in.
the supplementary material of [26]. In this case \( \mathbb{1} \not\in \text{span}\{\ket{x_i}\bra{y_i}\}\) and \( P_1, P_2 \in C(\mathcal{X}, \mathcal{Y}) \) are (entanglement-assisted) distinguishable. To see the latter define two states

\[
\rho_1 = (P_1 \otimes \mathbb{1}) \left( \frac{1}{d} \mathbb{1} \right) \mathbb{1} = \frac{1}{d} \sum_i \ket{i} \bra{i} \otimes \ket{x_i}\bra{x_i};
\]

(8)

\[
\rho_2 = (P_2 \otimes \mathbb{1}) \left( \frac{1}{d} \mathbb{1} \right) \mathbb{1} = \frac{1}{d} \sum_i \ket{i} \bra{i} \otimes \ket{y_i}\bra{y_i}.
\]

We need to check whether \( \text{supp}(\rho_1) \cap \text{supp}(\rho_2) = \{0\} \). We have

\[
\text{supp}(\rho_1) = \text{span}\{\ket{i} \otimes \ket{x_i}\}\};
\]

(9)

\[
\text{supp}(\rho_2) = \text{span}\{\ket{i} \otimes \ket{y_i}\}\}.
\]

Take \( \ket{\varphi} \in \text{supp}(\rho_1) \cap \text{supp}(\rho_2) \), then there exist numbers \( \alpha_1, \ldots, \alpha_m \) and \( \beta_1, \ldots, \beta_m \) such that

\[
\ket{\varphi} = \sum_i \alpha_i \ket{i} \otimes \ket{x_i} = \sum_i \beta_i \ket{i} \otimes \ket{y_i}.
\]

(10)

As \( \ket{x_i} \) and \( \ket{y_i} \) are linearly independent for all \( i = 1, \ldots, k \), then \( \ket{\varphi} = 0 \).

Therefore from Theorem 1 we obtain that \( P_1 \) and \( P_2 \) are perfectly distinguishable by a finite number of uses. Non-existence of the parallel scheme follows from Corollary 1 that is \( P_1 \) and \( P_2 \) cannot be distinguished in the parallel scheme as there exists a quantum state \( \rho \in \mathcal{D}(\mathcal{X}) \) such that \( \rho \in \text{span}\{\ket{x_i}\bra{y_i}\}\). The algorithm finding the state \( \rho \) will be presented in Section 5.

\[
\begin{array}{c}
|\psi_{in}\rangle \\
\Phi_{U_i}
\end{array} \xrightarrow{P_1/P_2} \begin{array}{c}
|\rangle \\
\Phi_{U_i}
\end{array} \xrightarrow{P_1/P_2} \begin{array}{c}
|\rangle \\
\Phi_{U_i}
\end{array} \xrightarrow{\text{decision}}
\]

**Figure 3.** Adaptive discrimination scheme

Now we focus on the adaptive scheme for perfect discrimination between \( P_1 \) and \( P_2 \) which is depicted in Figure 3. The top register corresponds to the space \( \mathcal{X} \) while the second and third registers correspond to spaces \( \mathcal{Y} \) and \( \mathcal{Z} \) respectively where each of these spaces is \( \mathbb{C}^3 \). Our goal is as follows. Before the final use of the black box we would like to obtain states \( \ket{\xi_i} \) and \( \ket{\eta_k} \) for which \( (P_1 \otimes \mathbb{1}) (\ket{\xi_i}\bra{\xi_i}) \) and \( (P_2 \otimes \mathbb{1}) (\ket{\eta_k}\bra{\eta_k}) \) are orthogonal. Therefore we need to find processing \( \Phi_i \) for which

\[
\sum_i \ket{i} \bra{i} \otimes \ket{\xi_i}\bra{\xi_i} = \sum_i \ket{i} \bra{i} \otimes \Phi_i((P_1 \otimes \mathbb{1}) (|\psi_{in}\rangle\langle\psi_{in}|))
\]

(11)

\[
\sum_i \ket{i} \bra{i} \otimes \ket{\eta_k}\bra{\eta_k} = \sum_i \ket{i} \bra{i} \otimes \Phi_i((P_2 \otimes \mathbb{1}) (|\psi_{in}\rangle\langle\psi_{in}|))
\]

where \( |\psi_{in}\rangle \) is the input state for the discrimination procedure.

The scheme for discrimination between \( P_1 \) and \( P_2 \) is as follows. First, using the fact that \( \text{rank} (\text{span}\{\ket{x_i}\bra{y_i}\}) < 9 \), we can find a nonzero matrix
\( A \in L(\mathcal{X}) \) such that

\[ A \perp \text{span}\{\langle x_i | y_i \rangle\}_i. \]

From the singular value decomposition we can write \( A = U \Sigma V^\dagger \). Next, find vectors \( |\xi\rangle, |\eta\rangle \in Y \otimes Z \) as \( |\xi\rangle = |U \sqrt{\Sigma}\rangle \) and \( |\eta\rangle = |V \sqrt{\Sigma}\rangle \). We can see that they fulfill the condition

\[ \text{Tr}_Z |\xi\rangle \langle \eta| = A. \]

Let \( |\xi\rangle = \frac{|\xi\rangle}{\|\xi\|} \) and \( |\eta\rangle = \frac{|\eta\rangle}{\|\eta\|} \).

Now we present the algorithm for the adaptive discrimination between \( P_1 \) and \( P_2 \).

1. As the input state to the discrimination we use the maximally entangled state on first two registers, that is \( |\psi_{in}\rangle = \frac{1}{\sqrt{d}} |1_l\rangle \rangle \). Then we perform the unknown measurement on the first register, either \( P_1 \) or \( P_2 \), and obtain a label \( i \). At the same time on the second register we obtain the state either \( |\psi_i\rangle \) or \( |\varphi_i\rangle \in Y \). Using the property in Eq. (7) one can note that

\[ |\langle \psi_i | \varphi_i \rangle| = \text{Tr}(A)^2 = \frac{1}{2}. \]

2. Basing on the label \( i \) we perform an isometric channel \( \Phi_{U_i}(\cdot) = U_i \cdot U_i^\dagger \) for \( U_i \in U(Y, Y \otimes Z) \) such that

\[ U_i |\psi_i\rangle = e^{i\theta_i} |\xi\rangle \]

\[ U_i |\varphi_i\rangle = |\eta\rangle \]

where \( \theta_i = \beta - \alpha_i \) for \( \langle \psi_i | \varphi_i \rangle = r_i e^{i\alpha_i} \) and \( \langle \xi | \eta \rangle = r e^{i\beta} \).

3. After performing the isometric channel we have a new third register \( Z \). Then we perform the unknown measurement on the second register \( Y \) and obtain a label \( j \).

4. Finally, we measure the third register by some known measurement and make a decision whether in the black box there was either \( P_1 \) or \( P_2 \).

5. Numerical results

In this section we study numerically the distinguishability of random POVMs with rank-one effects. We check the conditions for perfect distinguishability. To choose at random a POVM of dimension \( d \) with \( m \) rank-one effects we take a Haar random isometry matrix of dimension \( d \times m \). Then we take projectors onto the columns \( \{\langle x_i | y_i \rangle\}_{i=1}^m \) of this matrix and obtain a POVM with effects \( \{\langle x_i | x_i \rangle\}_{i=1}^m \).

Let \( P_1 \) and \( P_2 \) be POVMs with effects \( \{\langle x_i | y_i \rangle\}_{i=1}^m \) and \( \{\langle y_i | y_i \rangle\}_{i=1}^m \), respectively. If \( m = d^2 \), then \( \mathbb{I} \in \text{span}\{\langle x_i | y_i \rangle\} \) and therefore any two random rank-one POVMs cannot be distinguished perfectly by any finite number of uses. If \( d \leq m < d^2 \), then \( \mathbb{I} \notin \text{span}\{\langle x_i | y_i \rangle\} \). Hence there exists a finite number \( N \) of uses which allows for perfect distinguishability iff \( P_1 \) and \( P_2 \) are (entanglement-assisted) disjoint. Fortunately, we have the following lemma.
Lemma 1. Consider two independently chosen at random POVMs with rank-one effects. Then with probability one they are (entanglement-assisted) disjoint.

Proof. Define two states

\[
\rho_1 = (P_1 \otimes 1) \left( \frac{1}{d} |1\rangle \langle 1| \right) = \frac{1}{d} \sum_i |i\rangle \otimes |x_i\rangle \langle x_i|;
\]

\[
\rho_2 = (P_2 \otimes 1) \left( \frac{1}{d} |1\rangle \langle 1| \right) = \frac{1}{d} \sum_i |i\rangle \otimes |y_i\rangle \langle y_i|.
\]

We need to check whether \(\text{supp}(\rho_1) \cap \text{supp}(\rho_2) = \{0\}\). We have

\[
\text{supp}(\rho_1) = \text{span}\{i\rangle \otimes |x_i\rangle\};
\]

\[
\text{supp}(\rho_2) = \text{span}\{i\rangle \otimes |y_i\rangle\}.
\]

Take \(|\varphi\rangle \in \text{supp}(\rho_1) \cap \text{supp}(\rho_2)\), then there exist \(\alpha_1, \ldots, \alpha_m\) and \(\beta_1, \ldots, \beta_m\) such that

\[
|\varphi\rangle = \sum_i \alpha_i |i\rangle \otimes |x_i\rangle = \sum_i \beta_i |i\rangle \otimes |y_i\rangle.
\]

As it holds that for random POVMs \(|x_i\rangle\) and \(|y_i\rangle\) are linearly independent with probability one for all \(i = 1, \ldots, k\), then \(|\varphi\rangle = 0\). □

Knowing that for \(m < d^2\) two POVMs with rank-one effects can always be distinguished perfectly by a finite number of uses, now we are interested when it suffices to use the parallel scheme, instead of the adaptive one. From Theorem 1 we know that if there exists a positive operator \(\rho \in \text{span}\{|x_i\rangle \langle y_i|\}\), then we need to use the adaptive scheme. Simple numerical calculations show that there exist pairs of qubit POVMs with 3 rank-one effects which can be distinguished perfectly only by the adaptive scheme. Moreover, the probability of finding a pair of POVMs with this property is roughly equal to \(\frac{4}{10^5}\).

Now we proceed to studying the distinguishability of randomly chosen rank-one POVMs in higher dimensions depending on the number of effects. We study this problem numerically for the input dimension \(d = 7\) and the number of effects \(d < m < d^2\). The procedure is as follows. We sample \(N = 10^6\) pairs of random POVMs in a manner explained at the beginning of this section. For further details on sampling we refer the reader to [27,28].

In order to check whether the condition stated in Corollary 1 is fulfilled, we introduce an iterative algorithm. First, we construct a projection operator \(P\) on the space \(\text{span}\{|x_i\rangle \langle y_i|\}_{i=1}^m\) and choose an initial operator \(X \in L(X_d)\). We project \(X\) onto the subspace given by \(P\) obtaining some operator \(Y\). We substitute the operator \(X\) with the density operator closest to \(Y\) and repeat this procedure until it converges or a predefined number of steps is reached. The final step is to check whether the resulting operator is of full rank.

Figure 4 shows numerically found probability of finding a positive operator in the subspace defined in Corollary 1 as a function of the number of effects of POVMs. As we can see in the figure, as the number of effects increases, so does this probability. This is in agreement with previous results. On the one hand for the case when \(m = d\), we have a von Neumann POVM and we have
Figure 4. Numerically estimated lower bound for the probability $p_\rho$ of an event that for two randomly sampled POVMs with rank-one effects the adaptive scenario is necessary for achieving perfect discrimination. The probability is plotted as a function of the number of effects $m$ for the dimension $d = 7$. The number of samples per point is $N = 10^6$.

shown [13] that such measurements can always be distinguished in a finite number of steps in parallel. On the other hand, when we have $m = d^2$, then $\text{span}\{ |x_i\rangle\langle y_i| \}_i$ gives the entire space $\mathbb{C}^d$ and we are guaranteed to find the identity operator in it, which implies that perfect distinguishability cannot be obtained for any finite number of uses. In general, we are more likely to need to utilize the adaptive scheme for perfect discrimination when the number of effects of POVMs is close to $d^2$.

6. Conclusions

In this work we studied the problem of discriminating POVMs with rank-one effects. This class of measurements requires a more careful approach compared to von Neumann POVMs or even general projective measurements. We show that for this class of measurements there exist instances where the adaptive discrimination scheme is optimal. This is contrary to von Neumann POVMs, in which the parallel scheme is always optimal. We illustrate this result using a special class of POVMs – the symmetric information complete POVMs. For a given input dimension $d$ we study the discrimination between a SIC POVM and the same SIC POVM, but with permuted effects. This allows us to construct a simple example of two quantum channels which can be perfectly discriminated in a finite number of steps but require an adaptive scheme. We state the construction of such a discrimination scheme explicitly. Finally, we provide some numerical insight on the probability of randomly sampling a pair of POVMs with rank-one effects which can be distinguished only in the adaptive scenario.
