Abstract. Global floodplain mapping has rapidly progressed over the past few years. Different methods have been proposed to identify areas prone to river flooding, resulting in a plethora of available products. Here we assess the potential and limitations of two main paradigms and provide guidance on the use of these global products in assessing flood risk in data-poor regions.

1 Premise

As economic losses and fatalities caused by river flooding have dramatically increased over the past decades (Winsemius et al., 2016), there has been much progress in the development of analytical tools for the identification of the areas that can be potentially flooded (Ward et al., 2015; Dottori et al., 2018; Nardi et al., 2019). This progress has also been accelerated by the adoption of the Sendai Framework for Disaster Risk Reduction and the Warsaw International Mechanism for Loss and Damage Associated with Climate Change Impacts (Ward et al., 2015). As such, more and more scientists, experts, and practitioners use global floodplain maps in data-poor regions for the identification of flood risk hotspots or the mapping of flood-prone areas (Sampson et al., 2015; Ward et al., 2015; Winsemius et al., 2016; Dottori et al., 2018; Nardi et al., 2019).

2 Hydrological mapping

There are two main paradigms to map flooding. The traditional paradigm is (implicitly or explicitly) based on a definition of the floodplain as the area falling within the extent of a given flood event. In this hydrological paradigm, a range of synthetic events with a given probability of occurrence or return period (Pappenberger et al., 2013; Ward et al., 2015; Dottori et al., 2018), such as the 1-in-200-year flood event, is typically estimated via hydrological modelling or statistical analysis of flood data.

This synthetic event is then propagated along the river with hydrodynamic models to estimate the corresponding inundated areas. The hydrological paradigm has been widely used across multiple places and scales (Ward et al., 2015; Dottori et al., 2018), including large-scale flood hazard modelling in data-poor regions in Africa (Fig. 1). While flood inundation modelling has been successful in simulating historical events (Schumann et al., 2016), large uncertainties come into play when used to simulate synthetic events (Di Baldassarre, 2012). The estimation of a flood hydrograph with a given return period, for example, is extremely uncertain, as time series of flood data are hardly ever available, especially in data-poor areas (Blöschl et al., 2013). Trigg et al. (2016) compared flood maps produced by six hydrological models in Africa and found more disagreement than agreement.
Figure 1. Hydrological vs. hydromorphic flood mapping in Africa. Continental floodplain mapping using an hydrological approach (in blue) with a return period of 200 years (Dottori et al., 2016). The floodplain areas derived with the hydromorphic approach (in green) are based on the GFPLAIN250m dataset4 (Nardi et al., 2019). The inset shows estimated flood-prone areas in Kinshasa (Democratic Republic of the Congo) as well as the Global Man-made Impervious Surface (GMIS) layer (Brown de Colstoun et al., 2017) depicting urban areas (in yellow) and urban areas in floodplains (in red).

3 Hydrogeomorphic mapping

An alternative paradigm to map flooding is based on a definition of floodplains as distinguished landscape features that have been historically shaped by the accumulated effects of floods of varying magnitudes and their associated hydrogeomorphic processes (Nardi et al., 2006; Dodov and Foufoula-Georgiou, 2006). In this hydrogeomorphic paradigm, floodplains are identified directly from the topography (Nobre et al., 2011; Nardi et al., 2019), which is assumed to have been shaped by past flooding events, and building on the concept of fractal river basins (Rodríguez-Iturbe and Rinaldo, 2001) or hydrogeomorphic theories (Bhowmik, 1984; Tarboton et al., 1988). This paradigm does not require the estimation of a synthetic flood hydrograph and consistently identifies flood-prone areas across different places (Manfreda et al., 2014; Nardi et al., 2018; Annis et al., 2019). Also, with the recent development of global digital terrain models (DTMs; Ward et al., 2015; Nardi et al., 2019) and EO-based (Earth-observation-based) cloud computing platforms (Pekel et al., 2016), worldwide mapping of floodplain areas is a reality, and these global maps can be derived from a standard PC with a single click and limited computation time. Hence, it allows easily detecting floodplains, and it is a useful tool for a variety of environmental and socio-economic analyses at a large or global scale.
Table 1. Advantages and limitations of the two paradigms in mapping floodplain areas.

| Pros |
| --- |
| Less sensitive to DEM inaccuracies (Annis et al., 2019; Nardi et al., 2019). Floodplains are defined based on a specific probability of occurrence, this allows cost–benefit analyses and risk assessment (Winsemius et al., 2016). It can explicitly account for the role of hydraulic structures, e.g., flood gates, or climate change. It provides additional variables, such as maximum flow depth, velocity, and volume useful for some applications. Flood hazard maps at European and global scale by the Joint Research Center (JRC) https://data.jrc.ec.europa.eu/collection/id-0054 (last access: 19 May 2020) (Dottori et al., 2016) Global high-resolution dataset of Earth’s floodplains (GFPLAIN250m) https://figshare.com/articles/GFPLAIN250m/6665165/1 (last access: 19 May 2020) (Nardi et al., 2019) |

| Cons |
| --- |
| More sensitive to data scarcity. Time series of flood data are only seldom available and often too short for a robust estimation of a design flood (Blöschl et al., 2013). Computationally expensive. Variable over time; e.g., any interventions would require an update of the hydrodynamic model. More sensitive to data scarcity, as it does not require any time series. Computationally efficient (Annis et al., 2019). More consistent over time; e.g., floodplain is identified as if protection measures are not possible. This can be seen as an advantage, as erring on the side of least consequence (and total protection is impossible anyway). Scaling laws have limitations in dry climates. |

4 Comparing hydrological and hydrogeomorphic mapping

Figure 1 shows, as an example, floodplains of the African continent derived with both paradigms (Dottori et al., 2016; Nardi et al., 2019), while its insert compares them in the area around the city of Kinshasa, Democratic Republic of the Congo. International development banks; water sector organizations; and national and international bodies mandated with disaster risk reduction, sustainable development, and humanitarian response use these global maps in data-poor regions for mapping flood risk hotspots (Ward et al., 2015). To provide guidance in using these global products, we list limitations and advantages of the products derived using the two main paradigms in Table 1. This comparison focuses on the use of these global maps for the identification of flood-prone areas in data-scarce regions. It should be noted that the above paradigms have other purposes than flood mapping. Hydrological mapping is often carried out in order to derive probabilistic hazard metrics for risk assessment (e.g. Winsemius et al., 2016), while hydrogeomorphic maps can be used to support studies of anthropogenic pressure on rivers, such as floodplain connectivity, as well as human–flood interactions (Lindersson et al., 2020).

5 Conclusions

Both paradigms are based on consolidated theories, and they have opposite advantages and uncertainties (Table 1). Thus, we argue that these maps are complementary, and they should be exploited following the precautionary principle (Foster et al., 2000), which is an important component of much of the environmental legislation in the Western world. The principle calls for erring on the side of least consequences. In this context, this means that the identification of flood-prone areas in data-poor regions should consider flood inundation areas derived by the two paradigms. The insert of Fig. 1, for instance, highlights (in red) the urban areas falling within the hydrological and/or hydrogeomorphic flood map. While, for the sake of simplicity, our example considered only two global maps, the precautionary principle calls for using all existing flood maps. In this case, the growing availability of EO data (Schumann et al., 2009; Pekel et al., 2016; Lindersson et al., 2020) offers a great potential to test several maps and identify the (most credible) ones that can then be used to estimate flood-prone areas in data-poor regions.
