This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Molecular Dynamics Simulation of Spin-lattice NMR Relaxation in Poly-L-lysine Dendrimers. Manifestation of the Semiflexibility Effect.

NMR relaxation experiments are widely used to investigate the local orientation mobility in dendrimers. In particular, the NMR method allows one to measure the spin-lattice relaxation rate, $1/T_1$, which is connected with the orientational autocorrelation function (ACF) of NMR active groups.

We calculate the temperature ($\Theta$) and frequency ($\omega$) dependences of the spin-lattice NMR relaxation rates for segments and NMR active CH$_2$ groups in poly-L-lysine (PLL) dendrimers in water, on the basis of full-atomic molecular

dynamics simulations. It is shown that the position of the maximum of $1/T_1(\omega)$ depends on the location of the segments inside the dendrimer. This dependence of the maximum is explained by the restricted flexibility of the dendrimer. Such behavior has been predicted recently by the analytical theory based on the semiflexible viscoelastic model.

The simulated temperature dependences of $1/T_1$ for terminal and inner groups in PLL dendrimers of $n = 2$ and $n = 4$ generations dissolved in water are in good agreement with the NMR experimental data, which have been obtained for these systems previously by us. It is shown that in the case of PLL dendrimers, the traditional procedure of the interpretation of NMR experimental data - when smaller values of $1/T_1$ correspond to higher orientation mobility - is applicable to the whole accessible frequency interval only for the terminal groups. For the inner groups, this procedure is valid only at low frequencies.

INTRODUCTION

Dendrimers are perfect, tree-like macromolecules with a well-controlled chemical structure, which have been synthesized more than 30 years ago. Due to their spherical symmetry and compactness, on the one hand, and their softness, on the other, they are intermediate entities between colloids and linear polymers. They can be used in various industrial applications, such as biomedicine, energy harvesting, catalysis, and other fields.
The relaxation properties of dendrimers are of considerable importance in many practical applications.\textsuperscript{19-23} Even for a single dendrimer macromolecule, there are many relaxation processes with different length and time scales, starting from the rotation as a whole to the local segmental mobility. Different experimental methods are used to describe distinctive features of dendrimers (see e.g. Refs. 24-26).

NMR relaxation experiments are widely used to study local orientation mobility in dendrimers.\textsuperscript{27-38} In particular, the NMR method allows one to measure the spin-lattice relaxation rate, $1/T_1$, which is connected with the orientational autocorrelation function (ACF) of NMR active groups.

The traditional approach to estimate the mobility of NMR active groups is the measurement of $1/T_1$ at a fixed temperature and frequency.\textsuperscript{13,27-29} In this approach, the lower $1/T_1$ value corresponds to the higher mobility. However, Pinto et al.\textsuperscript{37} have shown that the application of this approach can lead to misinterpretations. It has been experimentally established for poly(aryl ether) dendrimers, that a direct correlation exists only between the spin-spin relaxation time ($T_2$), or the nuclear Overhauser effect (NOE), and the mobility of the NMR active groups. These characteristics have a monotonic dependence on the layer number in the dendrimer. However, $1/T_1$ has a non-monotonic layer number dependence at room temperature. The reason for this behavior is the fact that the dependence of $1/T_1$ on a reciprocal temperature has a maximum.\textsuperscript{39} Therefore, the
mentioned procedure can be applied only when the measured $1/T_1$ values are located on the left side of the maximum. In particular, this situation is realized in solutions of linear polymers. However, for dendrimers the position of the measured $1/T_1$ values with respect to the maximum can depend on the chemical structure of the dendrimer and on the location of the NMR active groups inside the dendrimer. As reported for poly(aryl ether), the non-monotonic behavior takes place due to the fact, that the values of $1/T_1$, measured for different layers, correspond to different sides of the temperature dependence with respect to the maximum. Similar behavior was observed for other dendrimers, as well. Therefore, for the correct interpretation of the $1/T_1$ data of dendrimers, the temperature dependence of $1/T_1$ is necessary.

Although there are many experimental works on the NMR relaxation in dendrimers, the number of theoretical investigations in this field is insufficient. As a rule, the theory considers the frequency dependence of $1/T_1$ at a constant temperature in contrast to the NMR experiments, where the temperature dependence at a fixed frequency, $\omega$, is studied. In this case, the maximum is observed on the frequency dependence of the reduced spin-lattice relaxation rate of $^1$H atoms:

$$\left[ \frac{1}{T_{1H}}(\omega) \right] = \frac{A_\omega \omega}{T_{1H}(\omega)},$$

(1)
where $A_0$ is a constant, which is insensitive to the temperature or frequency, and is determined by the type of a NMR active group.

Recently, some progress has been obtained in the theoretical studies of the orientational mobility of dendrimers,\textsuperscript{41-45} which provides an insight into the factors influencing the position of the maximum.\textsuperscript{46-47} In particular, it has been established,\textsuperscript{46} that the frequency dependence of $[1/T_1]$ for a labeled segment of a dendrimer is determined by three processes with different characteristic times. The first process corresponds to the local reorientation motions of the segment with the relaxation time, $\tau_{\text{loc}}$, which does practically not depend on the dendrimer size and on the topological location of the segment. The second process correlates with the rotation of a dendrimer branch that originates from this segment, where the characteristic time, $\tau_{\text{br}}$, of this process depends only on the branch size. The last process is the rotation of a dendrimer as a whole with the characteristic time, $\tau_{\text{rot}}$, which depends on the dendrimer size. These results were obtained for the following dendrimer models: (i) the viscoelastic model consisting of the Gaussian subchains, and (ii) the freely-joined bead-rod model. The first model was considered in terms of the analytical theory, while the second one was simulated by the Brownian dynamics method. Dendrimers up to the generation number $n = 4$ were studied.

On the basis of these results, the frequency dependences of $[1/T_1]$ for segments of dendrimer belonging to different dendrimer layers were calculated.
For both models, the independence of $\omega_{\text{max}}$ from $n$ and from the location of the segment inside a dendrimer was demonstrated. This independence is explained by the fact, that $\omega_{\text{max}}$ is mainly determined by the local reorientation motions of the segment. Therefore, one can expect\textsuperscript{39} that the position of the temperature maximum of $[1/T_1]$ at $\omega = \text{const}$ is also insensitive to $n$ and to the segment location. However, this prediction does not agree with the experimental data.\textsuperscript{32,35-37}

It has been assumed,\textsuperscript{47} that this discrepancy is connected with a restricted flexibility (semiflexibility) of a dendrimer. The effect of the dendrimer semiflexibility has been introduced into the viscoelastic model through the correlations between orientations of segments belonging to different dendrimer layers,\textsuperscript{48-50}

$$ |\langle u_i, u_j \rangle| = q^k, \quad (2) $$

where $u_i$ and $u_j$ are unit vectors directed along the $i$th and $j$th segments separated by $k$th segments and a parameter of semiflexibility in this model, $q$, is the average cosine of the angle between neighbouring segments. Indeed, the calculations of the frequency dependence of $[1/T_1]$ for the dendrimer segments have shown that incorporation of the restricted flexibility into the model leads to the dependence of $\omega_{\text{max}}$ on the dendrimer layer number of the labeled segment.\textsuperscript{47} The analysis has demonstrated, that the decrease of flexibility leads to a corresponding decrease of the contribution of local processes to the frequency dependence of $[1/T_1]$, as well
as to the increase of the contribution of second process, connected to the rotation of a dendrimer branch originating from a labeled segment.

It is necessary to bear in mind, however, that these conclusions have been drawn for the viscoelastic model, where the volume and hydrodynamic interactions are not taken into account. Moreover, the viscoelastic model describes incorrectly the third process, i.e. the rotation of a dendrimer as a whole.\textsuperscript{46}

In the present work, we study the behavior of $[1/T_1]$ for segments of the poly-L-lysine (PLL) dendrimer on the basis of the full-atomic molecular dynamic (MD) simulations. It is shown, that these dendrimers exhibit different positions of the maxima of the $1/T_1$ frequency and temperature dependences for terminal and inner segments. We explain such difference by the restricted flexibility of the PLL dendrimers.

This paper is structured as follows: in Section II we briefly describe the model and simulation details. Section III is devoted to our results and their discussion. Eventually, Section IV contains the conclusions. Some calculation details are presented in APPENDICES A and B.

II. MOLECULAR DYNAMIC SIMULATION DETAILS

The chemical structure of PLL dendrimers is shown in Fig. 1. There are two segments originating from every branching point, which are characterized by
different lengths. The inner longer segments are about 2.5 times larger than the shorter ones. The length ratio of terminal segments is close to 5.

In this paper, the numeration of dendrimer layers, \( m \), in every dendrimer starts from the *periphery* to the core, i.e. \( m = 0 \) corresponds to the terminal layer and \( m = n \) corresponds to the core (see Fig. 1).

**Figure 1** The chemical structure of the \( n = 1 \) generations PLL dendrimer. The solid blue and green arrows are the vectors connecting C atoms of branching points for short and long inner segments, respectively. The dotted arrows are the vectors connecting C atoms of terminal branching points and N atoms of terminal \( NH_3 \) groups. \( m \) is the dendrimer layer number.

The detailed description of the full-atomic model of the PLL dendrimer used in this work, and the simulation method, including the preparation and
equilibration of the system, have been given in our previous work.\textsuperscript{51} In brief, the dendrimers of \( n = 2 - 5 \) generations with protonated \( \text{NH}_3^+ \) terminal groups, were studied in the dilute water solution. Some parameters of the dendrimers are collected in Tab. 1. The cubic simulation box contains a single dendrimer molecule and water molecules together with \( \text{Cl}^- \) counterions. The number of \( \text{Cl}^- \) counterions is equal to the number of charged \( \text{NH}_3^+ \) terminal groups in the dendrimers. For simulation of the water molecules, a TIP3P model\textsuperscript{52} was used. The periodical boundary conditions and the Amber99sb-ildn force field were used,\textsuperscript{53} and calculations were performed in the NPT ensemble. Trajectories at 300 K for \( n = 2 - 5 \) and at \( \Theta = 283, 323, 343 \) and 363 K for \( n = 2 \) and 4 were obtained. Here and thereafter, \( \Theta \) is the absolute temperature. The Gromacs-4.5.5 package was used for our simulations.\textsuperscript{54} First, 50 ns of each MD simulation were applied for equilibration of the system, and finally 150 ns for calculations of the system characteristics. The sizes of the \( n = 2 - 4 \) dendrimers, obtained from our simulation, are in good agreement with the experimental data.\textsuperscript{55} Our results for the \( n = 3 \) dendrimer agree also with those obtained in Ref.\textsuperscript{56}.

In the PLL dendrimer, the lengths of segments in the same dendrimer layer are different in contrast to the theoretical model,\textsuperscript{47} where all segments have the same length. We believe that this difference is not important for the effect of the semiflexibility on the segmental orientation mobility. This assumption is supported
by similar characteristics of the orientation mobility of the long and short segments belonging to the same layer in the PPL dendrimer.\textsuperscript{40}

\textbf{Table 1.} \textit{Main characteristics of the PLL dendrimers.} \textit{n} is the number of generations, \textit{N\textsubscript{in}} is the number of inner segments and \textit{N\textsubscript{t}} is the number of terminal segments.

| \textit{n} | \textit{M}, g/mol | \textit{N\textsubscript{in}} | \textit{N\textsubscript{t}} |
|------------|------------------|-----------------|-----------------|
| 2          | 2028             | 15              | 16              |
| 3          | 4095             | 31              | 32              |
| 4          | 8229             | 63              | 64              |
| 5          | 16496            | 127             | 128             |

\textit{Semiflexibility parameter}

In order to compare our simulation results with the predictions of the semiflexible viscoelastic theory,\textsuperscript{47} which were obtained for the semiflexibility parameter \( q = 0.45 \) in Eq. (2), it is necessary to estimate the value of \( q \) for the PLL dendrimer with the results of our MD simulation.

We have calculated the average angle, \( \theta \), between the neighboring segments belonging to two successive dendrimer layers (Tab. 2). The value of \( \theta \) averaged over different \( n \) values, are found to be equal to 119\(^\circ\), which corresponds to \( q = 0.48 \) in Eq. (2). This value is close to \( q = 0.45 \ (\theta = 117\(^\circ\)) \) used in Ref.\textsuperscript{47}. 
Therefore, we can compare directly our simulation results with the theoretical calculations performed in Ref.\textsuperscript{47}.

**Table 2.** *The average angle (θ) between the neighboring segments belonging to two successive dendrimer layers in PLL dendrimers with n = 2 – 5.*

| Θ, K | n = 2       | n = 3       | n = 4       | n = 5       |
|------|-------------|-------------|-------------|-------------|
| 283  | 118 ± 4     | -           | 122 ± 3     | -           |
| 300  | 118 ± 4     | 120 ± 2     | 120 ± 2     | 120 ± 2     |
| 323  | 119 ± 2     | -           | 121 ± 1     | -           |
| 343  | 118 ± 4     | -           | 120 ± 1     | -           |
| 363  | 118 ± 5     | -           | 120 ± 1     | -           |

**Theory of the spin-lattice NMR relaxation**

The spin-lattice $^1$H NMR relaxation for NMR active groups in terms of the dipole-dipole interaction of relaxation is given by the following equation,\textsuperscript{39}

$$\frac{1}{T_{1\text{ll}}}(\omega_{\text{H}}, \Theta) = A_0(J(\omega_{\text{H}}, \Theta) + 4J(2\omega_{\text{H}}, \Theta)),$$

(3)
where \( \omega_\text{H} \) is the angular frequency of the used spectrometer for \(^1\text{H} \) atom, the spectral densities \( J(\omega, \Theta) \) and \( J(2\omega, \Theta) \) are real parts of the Fourier transform of the second-order orientation ACF, \( P_2(t) \), for the vector between \(^1\text{H} \) atoms in the \( \text{CH}_2 \) groups, \( r_{\text{HH}} \) (see Fig. 2):\(^{39} \)

\[
J(\omega) = 2 \int_0^\infty P_2(t) \cos(\omega t) dt \quad \text{and} \quad J(2\omega) = 2 \int_0^\infty P_2(t) \cos(2\omega t) dt .
\]  

(4)

Here,

\[
P_2(t) = \frac{3}{2} \left( <u(t)u(0)> - \frac{1}{3} \right),
\]

(5)

where \( u(t) = r_{\text{HH}} / |r_{\text{HH}}| \) is a unit vector. The function \( J(\omega) \) was calculated from \( P_2 \) ACF numerically with Eq. (4). The details of the calculation are given in APPENDIX A.

If \( P_2(t) \) is represented by the sum of exponents,

\[
P_2(t) = \sum_l C_l^* \exp(-t / \tau_l^*),
\]

(6)

where \( C_l^* \) and \( \tau_l^* \) are the weights of the relaxation times, the spectral density can be expressed as

\[
J(\omega) = 2 \sum_l \frac{C_l \tau_l^*}{1 + (\omega \tau_l^*)^2}
\]

(7)

III. RESULTS AND DISCUSSION

Comparison with the analytical theory
The minimum length scale of the viscoelastic model corresponds to the length of a single segment. Therefore, to compare with the analytical theory it is necessary to study the reorientation of the unit vectors directed along the segments (Fig. 2), i.e. $u(t) = r_s(t) / |r_s(t)|$ in the PLL dendrimers. We consider the reduced relaxation rate, $[1/T_{1H}]$, given by Eq. (1) as well as in Refs. 46-47. The calculation methods of $[1/T_{1H}]$ at different frequencies $\omega$ for the segments belonging to different dendrimer layers, using the simulation data, are described in APPENDIX A.

**Figure 2.** Chemical structure of an internal segment (a) and a terminal segment (b). The green circles mark branching points. The black arrows correspond to the direction of $r_{HH}$ and $r_{CH}$ unit vectors of $CH_2$ groups, which are observed in the NMR relaxation. The red arrows are $r_{CC}$ and $r_{CN}$ vectors of CC and CN bonds, which are connected in the $CH_2$ group, and the dotted blue arrows mark the long segment vector, $r_s$. The orthogonal vector is determined
by the expression \( r_n = [r_{CC} \otimes r_{CN}] \)

Fig. 3 shows the frequency dependences of \([1/T_{1H}]\) for the segments belonging to different dendrimer layers of the PLL dendrimers with different \(n\). It can be seen that the position of \([1/T_{1H}]\) maximum \(\omega_{max}\) depends on the layer number, \(m\) (Fig. 3a). When \(m\) increases, \(\omega_{max}\) shifts towards lower frequencies.

This result agrees qualitatively with the predictions of the analytical theory for the semiflexible viscoelastic model of the dendrimer.\(^{47}\) Here we recall, that the flexible viscoelastic model predicts independence of \(\omega_{max}\) from \(m\).

As in the viscoelastic model, the simulated \(\omega_{max}\) for the terminal segments \((m = 0)\) are practically independent from \(n\) (Fig. 3b). Hence, we can use the value of \(\omega_{max}\) \((m = 0)\) as the reference point in order to compare the results of the analytical theory with the simulations. Fig. 4 shows the values of \(\omega_{max}/\omega_0\) for different \(m\) and \(n\) obtained from the theory\(^{47}\) for the semiflexible dendrimer and our simulation results. It can be seen, that the overall trend is the same: \(\omega_{max}/\omega_0\) decreases with increasing \(m\). However, there are some differences between the theory and the simulation. First, the simulation demonstrates that \(\omega_{max}\) for given \(m\) depends on the overall generation number \(n\) of a dendrimer, in contrast to the theory predictions about insensitivity of \(\omega_{max} (m = \text{const})\) to \(n\). Second, the theory predicts a more rapid decrease of \(\omega_{max}\) with \(m\) for \(m \geq 2\) than that obtained with the simulations.
Figure 3. Frequency dependences of $[1/T_{1H}]$ for the segments of lysine dendrimers. MD simulation results.
**Figure 4.** The position of the $[1/T_{1HH}]$ maxima for different $m$ and $n$. Dotted horizontal lines mark $\omega_{\text{rot}}$ and correspond to $n$ with the same color; $\omega_0 = \omega_{\text{max}} (m = 0)$. MD simulation and analytical theory$^{47}$ results.

The following connects these differences with the simplifications used in the viscoelastic dendrimer model. First, the model does not take into account the excluded volume and hydrodynamic interactions (the phantom and free-draining model). Therefore, the segments in this model do not “feel” the local concentration of surrounding segments in the dendrimer. However, this concentration can depend on $n$ for the segments with the same $m$, and affect their orientation mobility. Our previous simulation shows,$^{51}$ that the average density of PLL dendrimers grows with $n$. Therefore, the local concentration of dendrimer monomers in internal layers is expected to increase as well, which could lead to an increase of $\tau_{br}$ due to additional friction between the branch and other segments of the dendrimer and a decrease of $\omega_{\text{max}}$. 
The second defect of the viscoelastic model is its inability to describe correctly the contribution of the dendrimer rotation as a whole to the segment relaxation. The simulations of the coarse-grained dendrimer models\textsuperscript{46} in solution show, that this contribution can be quite significant. The values of $\tau_{\text{rot}}$ for the PLL dendrimers with $n = 2 - 5$ at 300 K, calculated in APPENDIX B, are collected in Tab. 3.

**Table 3.** *Characteristic times of the rotation PLL dendrimers as a whole, $\tau_{\text{rot}}$, at 300 K*

| $n$ | $\tau_{\text{rot}}$, ns |
|-----|-------------------------|
| 2   | 0.8±0.04                |
| 3   | 1.7±0.1                 |
| 4   | 4.2±0.2                 |
| 5   | 7.2±0.2                 |

If the orientational relaxation of a segment is determined only by the dendrimer rotation as a whole, $\omega_{\text{max}}$ will be equal to $\omega_{\text{rot}}$ related to $\tau_{\text{rot}}$ with the expression

$$\omega_{\text{rot}} \approx \frac{0.616}{\tau_{\text{rot}}}$$

(see e. g. page 203 of Ref. 57). The values of $\omega_{\text{rot}}$ for different $n$ are shown by horizontal dotted lines in Fig. 4. It can be seen, that for segments with $m = n$ the values of $\omega_{\text{max}}$ are equal to $\omega_{\text{rot}} (n)$, which means that the reorientation of the
segments lying close to the core is determined by the rotation as a whole. For lower $m$, the relation $\omega_{\text{max}}(m,n) > \omega_{\text{rot}}(n)$ means that the internal modes start to contribute to the segments reorientation. However, the observed splitting of $\omega_{\text{max}}$ for different $n$ and the same $m$ shows that the contribution of the rotation as a whole affects remarkably the value of $\omega_{\text{max}}$.

Finally, we can conclude that the shift of $\omega_{\text{max}}$ towards lower frequencies with the increase of $m$ observed in the simulations can be described by the effect of the semiflexibility, predicted by the analytical viscoelastic model.\textsuperscript{47} For the segments lying close to the dendrimer core, this shift is decreased due to the increased contribution of the dendrimer rotation as a whole.

**Spin-lattice NMR relaxation of CH$_2$ groups**

MD simulations of the full-atomic model allow the study not only of the reorientation of the segments, but also the mobility of NMR active groups. We focus mainly on the mobility of $r_{\text{HHH}}$ vectors in CH$_2$ groups (which are connected to N atoms) for PLL dendrimer in water. The temperature dependences of $1/T_{1H}$ for these $r_{\text{HHH}}$ vectors were measured in our NMR experiments.\textsuperscript{40}

The method of the spin-lattice NMR relaxation allows one to measure proton relaxation time, $T_{1H}$, separately for groups with different chemical shifts, i.e. with different peak positions of the $^1$H NMR spectrum. The value of the shift for the same group depends on the chemical structure of its environment. In principle, the NMR active groups located in different dendrimer layers may correspond to
different peaks. In particular, this situation is realized for poly(aryl ether) dendrimers.\textsuperscript{37} It allows the mobility in every dendrimer layer to be studied separately. In the case of the PLL dendrimer, there is a remarkable difference of the chemical shifts between terminal and inner CH\textsubscript{2}-N groups, but it is difficult to distinguish the difference between inner layers (see Supplementary Information).

Therefore, to compare the simulation data with the experimental spin-lattice relaxation rate for the inner CH\textsubscript{2}-N groups, $[1/T_{1\text{HH}}^{\text{inn}}]$, we have to use in Eq. (5) the function $P_2^{\text{inn}}(t)$ averaged over all inner groups:

$$P_2^{\text{inn}}(t) = \frac{\sum_{m=1}^{n} N_m P_2(t,m)}{\sum_{m=1}^{n} N_m},$$

(9)

where $N_m = 2^{n-m+1}$ is the number of long segments in the $m$th dendrimer layer.

We have calculated frequency dependences of $[1/T_{1\text{HH}}^{\text{inn}}]$ and $[1/T_{1\text{HH}}^{\text{ter}}]$ at different temperatures, $\Theta$, for CH\textsubscript{2} groups in PLL dendrimers by using Eqs. (3)-(5) and (9) with a unit vector $\mathbf{u}(t) = \mathbf{r}_{\text{HH}}(t) / |\mathbf{r}_{\text{HH}}(t)|$. Here, $[1/T_{1\text{HH}}^{\text{ter}}]$ depends on $\mathbf{r}_{\text{HH}}$ of the terminal long groups (see Fig. 2b). The details of the calculations are described in APPENDIX A.

For both studied dendrimers ($n = 2$ and 4) at all temperatures, the positions $\omega_{\text{max}}$ of the maximum of $[1/T_{1\text{HH}}]$ for the $\mathbf{r}_{\text{HH}}$ vectors of the CH\textsubscript{2} terminal groups are shifted to higher frequencies with respect to those of the CH\textsubscript{2} inner groups (Fig. 5). Therefore, the shift of $\omega_{\text{max}}$ with increasing dendrimer layer number, observed above for the segments, takes place also for the NMR active groups. We believe
that in both cases this shift is the manifestation of the dendrimer semiflexibility effect.

![Graph](image)

**Figure 5.** Frequency dependences of \([1/T_{1\text{H}}]\) for CH\(_2\) groups of inner and terminal segments of lysine dendrimers with \(n = 2\) and \(4\). The vertical dotted line indicates the frequency \((\omega_H/2\pi = 400\text{ MHz})\) corresponding to the spectrometer used in Ref.\(^{40}\).

For the same segments, the values of \(\omega_{\text{max}}\) for \(r_{\text{HH}}\) exceed those for \(r_s\) (Fig. 6). However, this difference is not connected with the different size of the CH\(_2\) groups and segments. Therefore, we have calculated the frequency dependences of the \([1/T_{1\text{H}}]\) functions for \(r_{\text{CC}}\), which has approximately the same length as \(r_{\text{HH}}\) (Fig. 6). It can be seen, that these dependences practically coincide with those for \(r_s\). At the same time, the frequency dependences of \([1/T_{1\text{H}}]\) for \(r_{\text{HH}}\)
are shifted towards higher values. We believe that this difference can be explained by the fact that the reorientations of the \( r_{HH} \) vectors correspond to transversal modes, in contrast to those of \( r_s \), which are determined by longitudinal modes. As has been shown in several studies (see e.g. Ref.\textsuperscript{58}), the transversal modes are considerably faster than the longitudinal ones.

![Figure 6](image.png)

**Figure 6.** Frequency dependences of \( 1/T_{1H} \) for \( r_{HH}, r_{CC}, \) and \( r_s \), calculated for inner and terminal segments of lysine dendrimers with \( n = 2 \) and \( n = 4 \) at 300 K

**Comparison with NMR experimental data**

Here we compare the results of the MD simulations with the experimental results obtained in our work.\textsuperscript{40} The circle frequency of the spectrometer, which is used in Ref.\textsuperscript{40} was \( \omega_{sys}/2\pi = 400 \text{ MHz} \). In Fig. 5 this frequency is marked by a vertical dotted line. The crossing points of the simulated frequency dependences of \([1/T_{1H}]\) at different temperatures with this line give the values of \([1/T_{1H}]\)
corresponding to those obtained experimentally. For direct comparison of our results with experimental data, it is necessary to know the value of $A_0$ in Eqs. (3). In the case of the CH$_2$ groups, this constant is given by the expression

$$A_0 = \frac{3}{10} \left( \gamma_n^2 \hbar^2 / r_{\text{HH}}^6 \right),$$

where $\gamma$ is a gyromagnetic ratio of $^1$H and $r_{\text{HH}}$ is the effective distance between protons. If we use the value of $A_0^{\text{theor}} = 0.56 \times 10^{10}$ s$^{-2}$, calculated from Eq. (10), we obtain a remarkable difference between the results of the MD simulation and the experimental data. This is a typical situation for dendrimers (see e.g. experimental results in Refs. 32,35,36). Due to this fact, the value of $A_0$ is considered as a fitting parameter and is determined by coincidence of the experimental and the simulated $1/T_{1\text{H}}$ data at 300 K. The values of $A_0^{\text{inn}} = 0.35 \times 10^{10}$ s$^{-2}$ and $A_0^{\text{ter}} = 0.51 \times 10^{10}$ s$^{-2}$ were obtained for the CH$_2$ groups, belonging to the inner segments and the terminal CH$_2$ groups, respectively. The answer to the question about the reasons for the difference between these values and $A_0^{\text{theor}}$ can be obtained only by quantum chemistry methods. We can suggest one possible variant: experimental values of $|r_{\text{HH}}|^2$ differ from theoretical ones, calculated using standard values of the C-H chemical bond and valence angle for CH$_2$ group. Fig. 7 shows the temperature dependences of $1/T_{1\text{H}}$, obtained with the simulation data using the corresponding values of $A_0$ and the experimental temperature dependences of $1/T_{1\text{H}}$. It can be seen, that the simulation results reproduce the experimental data. Unfortunately, because the accessible temperature interval is limited by the boiling and freezing
points of the solvent, this does not allow observation of all the maxima of $1/T_{1H}$.

For the inner groups, the function $1/T_{1H} (\Theta^{-1})$ has a maximum within the measured temperature interval. For the terminal groups, this maximum of $1/T_{1H}$ grows almost exponentially with increasing $\Theta^{-1}$.

![Plot of $1/T_{1H}$ vs. inverse temperature](image)

**Figure 7.** Plots of $1/T_{1H}$ vs. inverse temperature (1000/Θ) for terminal and inner CH$_2$ groups. The NMR experimental data$^{40}$ and the MD simulation results are shown.

The temperature dependences, $1/T_{1H} (\Theta^{-1})$, for the inner and terminal groups of the PLL dendrimers were obtained at the fixed frequency ($\omega_H/2\pi = 400$ MHz). However, the shape and the relative positions of the $1/T_{1H}(\Theta^{-1})$ curves depend not only on the location of the active groups inside a dendrimer, but on the spectrometer frequency $\omega_H/2\pi$, as well. In particular, consideration of the temperature dependence at different frequencies has been performed in Ref.$^{37}$

Using the calibration value of $A_0$, we obtained temperature dependences of $1/T_{1H}$ at $\omega_H/2\pi = 100$, 1000, and 1600 MHz (Fig. 8).
Figure 8. Plots of $1/T_{1H}$ vs. inverse temperature $(1000/\Theta)$ for terminal and inner CH$_2$ groups at different $\omega_H/2\pi = 100$, 1000 and 1600 MHz. MD simulation results.
At a smaller frequency $\omega_H/2\pi = 100$ MHz, the curves for the inner groups are located higher along the vertical axis, than those for terminal groups, within the whole temperature interval. At higher frequencies ($\omega_H/2\pi \geq 400$ MHz), these curves cross each other, where the crossing points are shifted to higher temperatures with increasing frequency.

As was mentioned in the INTRODUCTION, the traditional approach to characterize the mobility of different parts of dendrimers by NMR relaxation focuses on the comparison of the $1/T_{1H}$ values at the same (room) temperature (see e. g. Refs. 13, 27-29). It is assumed, that the lower value of $1/T_{1H}$ corresponds to the higher mobility. This assumption is completely correct if the measured $1/T_{1H}$ values are located on the left side of the $1/T_{1H}(\Theta^{-1})$ maximum. This case corresponds to the frequency $\omega_H/2\pi = 100$ MHz, when the curves of the inner groups or terminal groups are shifted to a larger value of $1/T_{1H}$ for $n = 4$ with respect to those for $n = 2$ the terminal ones as well as $1/T_{1H}$ points of inner groups larger value than ones of terminal groups for the same $n$. For higher frequencies ($\omega_H/2\pi \geq 1600$ MHz), there is an opposite situation: the values of $1/T_{1H}$ at $\Theta = 300$ K of the terminal groups occur to be larger than of the inner ones.

In principle, a qualitative comparison of the mobility of the inner and terminal groups in the same PLL dendrimer by $1/T_{1H}$ is possible for frequencies up to 1000 MHz. Fig. 9 shows the ratio of $(1/T_{1H}^{\text{ter}})/(1/T_{1H}^{\text{inn}})$ for different frequencies, calculated at $\Theta = 300$ K. It can be seen, that this ratio exceeds unity at low
frequencies and is less than unity at higher 1000 MHz frequencies. This result is caused by the fact that the large difference in orientational mobility of inner and terminal groups due to low flexibility of segments in the PLL dendrimers. However, this frequency will be lower than 400 MHz if the possibility is available to consider the $1/T_{1H}$ values of groups from the different inner layers. This result is expected due to $1/T_{1H}$ data for segments (see Fig. 3a). Quantitative comparison of the mobility of inner and terminal groups of the same dendrimer using $1/T_{1H}$ is possible also at frequencies lower than 400 MHz.

Thus, our results for PLL dendrimers confirm the conclusions of Ref. 37 that the traditional approach can lead to incorrect conclusions and, therefore, the features of temperature dependence of $1/T_1$ is important for the interpretation of the $1/T_1$ data for dendrimers.

![Figure 9](image.png)

**Figure 9.** The ratio of $(1/T_{1H}^{ter})/(1/T_{1H}^{inn})$ at $\Theta = 300 K$ vs. different frequencies.
Figure 10. Time dependences of $P_2$ obtained from the MD simulations for $r_{HH}$ (solid lines), $r_{CH}$ (dashed lines), and $r_{tr}$ (dotted lines) vectors in terminal (a, c) and inner (b, d) CH$_2$ groups (cf. Fig. 2a and 2b) at different temperatures.

Experimentally, the decrease of the angular frequency $\omega_H$ leads to a deterioration in the resolution of a spectrometer. This difficulty can be avoided by the use of $^{13}$C atoms to measure the NMR relaxation, because $\omega_H/\omega_C \approx 4$ for the
same spectrometer. The $1/T_{1C}$ function for carbon atoms is determined by the following equation,

$$1/T_{1C}(\omega_C) = A_0(C)[6J(4.97\omega_C) + J(2.97\omega_C) + 3J(\omega_C)], \quad (11)$$

and by Eqs. (4)-(5), where $u(t) = r_{CH}$ (see Fig. 2). In Fig. 10 are displayed the time dependences of $P_2$ ACF for the $r_{HH}$ and $r_{CH}$ vectors, which determine the frequency dependence of the $1/T_{1H}$ and $1/T_{1C}$ functions. It can be seen, that these functions practically coincide with each other and correspond to $P_2$ ACF for the $r_{tr}$ vector. Therefore, NMR relaxations for $^1H$ or $^{13}C$ atoms are determined by the same relaxation processes, and all conclusions for PLL dendrimers concerning $1/T_{1H}$ are valid for $1/T_{1C}$.

IV. CONCLUSIONS

The temperature and frequency dependences of the spin-lattice NMR relaxation rates ($1/T_1$) for the segments and the NMR active CH$_2$ groups in poly-L-lysine dendrimers in water have been calculated on the base of full-atomic molecular dynamics simulations. The comparison of the simulation results with the theoretical predictions for the viscoelastic model, developed recently in Ref. has been performed. It shows, that the observed dependence of the position of the $[1/T_1]$ maximum on the location of the segments inside the dendrimer can be explained by the effect of the restricted flexibility of a dendrimer. The same effect
can be responsible for the difference in the orientational mobility of the terminal and inner NMR active \text{CH}_2 groups in PLL dendrimers. This difference leads to the different temperature dependences of $1/T_{1H}$ for the terminal and inner groups, observed experimentally by us in Ref.\textsuperscript{40}. Our simulations reproduce the experimental data for $n = 2$ and $n = 4$ PLL dendrimers.

Since the differences in the temperature dependence of $1/T_{1H}$ for the inner and terminal groups have been observed also for other dendrimers,\textsuperscript{32,35} we can suppose that the restricted flexibility (semiflexibility) manifests itself in these cases, as well. The similar effect can be responsible also for the different temperature dependences of $1/T_{1H}$ for NMR active groups in different layers of poly(aryl ether) dendrimers.\textsuperscript{37}

In our work is discussed also the applicability of the traditional interpretation of the NMR experimental data, when the smaller values of $1/T_1$ correspond to the higher orientation mobility. We have confirmed the conclusion of Ref.\textsuperscript{37} to consider the temperature dependence of $1/T_1$ for the correct interpretation of the $1/T_1$ data for dendrimers. We have calculated the temperature dependences of $1/T_{1H}$ for inner and terminal groups in PLL dendrimers at different frequencies. It is shown, that the traditional procedure is applicable for comparison of the mobility of inner and terminal groups of different PLL dendrimers at the room temperature only at low frequencies (~ 100 MHz). At high frequencies ($\geq 1600$ MHz), the opposite situation is observed: the smaller values of $1/T_{1H}$ correspond to the lower mobility.
Concerning the mobility of the inner groups of the different PLL dendrimers, the procedure above is correct only at frequencies below ~ 400 MHz. In the same case of the terminal groups, the traditional approach can applied within the experimentally accessible frequency interval.

Qualitative comparison of the mobility of the inner and terminal groups in the same PLL dendrimer by $1/T_{1H}$ is possible for frequencies up to 1000 MHz. This result is caused by the fact that the large difference in orientational mobility of inner and terminal groups due to low flexibility of segments in the PLL dendrimers. However, this frequency will be lower than 400 MHz if the possibility is available to consider the $1/T_{1H}$ values of groups from the different inner layers ($m > 0$). Also, quantitative comparison of the mobility of inner and terminal groups of the same dendrimer using $1/T_{1H}$ is possible also at frequencies lower than 400 MHz.

Additionally, we have shown that the $^1$H or $^{13}$C NMR relaxations for PLL dendrimers are determined by the same relaxation processes. Therefore, the main conclusions concerning $1/T_{1H}$ are applicable also to $1/T_{1C}$. Thus, the use of these two methods provides mutually complementary information about molecular mobility in PLL dendrimers.
ACKNOWLEDGMENTS

Many thanks to Dr. Konstantin G. Lisunova for helpful discussions. This work is partially supported by the Russian Foundation for Basic Research (grants No 13-03-00524, 13-03-00728, and 14-03-00926) and the Government of the Russian Federation grant 074-U01. The simulations have been performed using the Lomonosov supercomputers at the Moscow State University and the resources of the computer center of Saint Petersburg State University.

APPENDIX A. Calculations of the frequency dependences of $1/T_{1H}$ functions.

To obtain $1/T_{1H}$ functions from $P_2$ ACF, we use numerical calculations on the base of Eq. (4) for spectral density, which determines $1/T_{1H}$ in Eq. (3). To improve the numerical calculation results, we approximate the tail of each $P_2$ ACF by one-exponential fitting and construct full $P_2^{\text{full}}$ with Eq. (A.1),

$$P_2^{\text{full}}(t) = \begin{cases} P_2(t); & (t \leq t_{\text{cut}}) \\ P_2(t = t_{\text{cut}}) \exp(-t / \tau_{\text{tail}}); & (t > t_{\text{cut}}) \end{cases},$$

(A.1)

where $t_{\text{cut}}$ is the cutting time for each $P_2$ ACF, $\tau_{\text{tail}}$ is the characteristic time, which is calculated from the finite slope of the $P_2$ ACF. For all curves, we use $t_{\text{cut}}$ given by the condition of $P_2(t_{\text{cut}}) \leq 0.01$.

This method is applied to the calculation of $[1/T_{1H}]$ functions. Initial data are presented for different vectors of PLL dendrimers at several temperatures, including Fig. A.1 and Tab. A.1 for $r_s$ vectors of the segments at 300 K, Fig. A.2
and Tab. A.2 for $r_{HH}$ vectors of the inner and terminal segments in the dendrimers with $n = 2$ and $4$ at $283, 300, 323, 343, 363$ K, and Fig. A.3 and Tab. A.3 for $r_{CC}$ vectors of the inner and terminal segments in the dendrimers with $n = 2$ and $4$ at $300$ K.

APPENDIX B. Characteristic times of rotation of PLL dendrimers as a whole at 300 K.

The characteristic time of rotation of the dendrimer as a whole can be obtained from the $P_1^{rot}$ autocorrelation function (ACF),\textsuperscript{41,42}

$$P_1^{rot} = \langle r_d(0) r_d(t) \rangle,$$  \hspace{1cm} (B.1)

where $r_d(t)$ is a unit vector along the direction from the core to terminal groups (i.e. to NH\textsubscript{3} charged group). The averaging in Eq. (B.1) is performed for all the terminal NH\textsubscript{3} groups. The calculated $P_1^{rot}$ ACF data for $n = 2$-5 generations PLL dendrimers at 300 K are shown in Fig. B.1.
**Figure B.1.** The time dependencies of $P_{1}^{rot}$ ACF for PLL dendrimers with $n = 2$-5 at 300 K. Dotted lines are the approximation of the $\ln(P_{1}^{rot})$ slope.

The slope of the $\ln(P_{1}^{rot})$ function corresponds to the reciprocal characteristic time of rotation of a dendrimer as a whole. The dotted lines are the approximation of the slope of $\ln(P_{1}^{rot})$ in Fig. B.1. The results of the calculations are collected in Tab. B.1.

**Table B.1.** Characteristic times of the rotation of PLL dendrimers as a whole, $\tau_{rot}^{n}$, at 300 K

| $n$ | $\tau_{rot}^{n}$, ns |
|-----|---------------------|
| 2   | 2.4±0.1             |
| 3   | 5.2±0.3             |
| 4   | 12.5±0.5            |
| 5   | 21.6±0.5            |
Additionally, we have to point out that the $P_2$ ACF appears in NMR relaxation and (B.1) decays faster than the $P_1$ ACF. To establish the appearance of $\tau_{rot}^R$ in $P_2$ ACF, we calculate $P_2^{rot}$ ACF for the same $r_d$ vector as in Eq. (B.1),

$$P_2^{rot}(t) = \frac{3}{2} \left( <r_d(t)r_d(0) > - \frac{1}{3} \right).$$  \hspace{1cm} (B.2)

In Fig. B.2, we check up the relationship

$$P_2^{rot}(t) = \left( P_1^{rot}(t) \right)^3$$  \hspace{1cm} (B.3)

The utilization of Eq. (B.3) seems to be valid for PLL dendrimers, as well. Hence, we can conclude that the rotation time which appears in $P_2$ ACF, $\tau_{rot}$, is expressed as

$$\tau_{rot} = \tau_{rot}^R / 3.$$  \hspace{1cm} (B.4)

The values of $\tau_{rot}$ are presented in Tab. 3.
