Abstract

Using an ab-initio molecular dynamics scheme (the Fireball scheme), we determined the equilibrium structure of intermediate size $\text{Si}_n\text{Ge}_m$ ($n + m = 71$) nanoclusters with/without hydrogen passivation on the surface. Due to the strong surface distortion, defect states are found to permeate the energy gap of $\text{Si}_n\text{Ge}_m$ clusters. However, the defect states are removed by adding H atoms on the surface of $\text{Si}_n\text{Ge}_m$ clusters, and the gap opens up to a few eV, indicating a blueshift for photoluminescence. It is also found that the radiative transition between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) states is enhanced by one to two orders of magnitude for $\text{Si}_n\text{Ge}_m$ nanoclusters with respect to the corresponding pure Si clusters. This significant increase of the emission probability is attributed to the strong overlap of HOMO and LUMO wavefunctions that are centered mostly on the Ge atoms.

I. INTRODUCTION

The optical properties of bulk Si and Ge are rather mediocre because the light emission in the bulk Si and Ge is a phonon-assisted indirect process. Therefore, to improve on the light emission feature in Si-based materials is a challenge for both the technological and the fundamental research.

The luminescence is a result of a significant overlap in electron and hole wave functions as the strength of the luminescence (i.e., the emission rate and quantum efficiency) depends on the extent of this overlap and the transition probability. Possible means to increase this overlap for the Si-based materials may be accomplished through, for example, alloying to change the band structure, impurities to produce the intermediate state through which the electron can recombine with the hole, or zone folding to yield the desired quasi-direct transition [1]. However, the most important breakthrough in this issue is the observation of the visible photoluminescence (PL) from porous Si [2, 3, 4] and Si quantum dots [5] which opens new possibility for fabricating visible light emitting device from Si-based materials. Structural analysis of porous Si is quite difficult. But several measurements have confirmed that the principal feature of porous Si consists of extremely fine structures which are small enough to exhibit quantum confinement effects [2, 4, 5]. Various theoretical works have been reported on Si nanowires [6, 7, 8, 9, 10] and Si clusters [11, 12, 13, 14, 15]. They clarified that the quantum confinement effects give rise to the change in the electronic structure and the optical properties and are the principle mechanism of the blueshift PL in porous Si and Si quantum dots.

There were experimental reports indicating that Ge quantum dots embedded in SiO2 glassy matrices [16] or in porous Si [17] show a strong room temperature luminescence. Theoretical studies on the structure and stability of Ge clusters [18], the polarizabilities of small Ge clusters [19], and the quantum confinement effect on excitons in Ge quantum dots [20] have also been reported. Since Ge has smaller electron and hole effective masses and a larger dielectric constant than the corresponding quantities for Si, the effective Bohr radius of the exciton in Ge is larger than that in Si, and the quantum confinement effect appears more pronounced in Ge than in Si [16, 17, 20, 21]. These results suggest that Si$_p$Ge$_m$ nanoclusters could be possible candidates to be used as components for nanoscale functional optical devices. In order to understand the physics of Si$_p$Ge$_m$ clusters, we performed an
ab initio molecular dynamics simulation for Si$_n$Ge$_m$ clusters of an intermediate size, and systematically studied their electronic and optical properties. There is no doubt that the mismatch effect dominating the electronic and optical properties in Si$_{1-x}$Ge$_x$ alloys may introduce interesting optical features in Si$_n$Ge$_m$ clusters. But one has to keep in mind that the surface distortion associated with the stabilizing of the Si$_n$Ge$_m$ clusters will also play an important role. Therefore the competition between the lattice mismatch and the surface distortion is the basic issue in our investigation. For this purpose, we studied Si$_n$Ge$_m$ clusters of an intermediate size with/without the hydrogen passivation. By comparing our results between the two sets of Si$_n$Ge$_m$ clusters, we found that the surface distortion plays an important role in the intermediate size of Si$_n$Ge$_m$ clusters but the mismatch effect dominates when Si$_n$Ge$_m$ clusters of the intermediate size are passivated by hydrogen atoms to eliminate the dangling bonds so as to lessen the effect of the surface distortion. We also found that the latter shows an enhancement of radiative transition and a blueshift in PL.

It should be noted that our simulations of the Si$_n$Ge$_m$ clusters without hydrogen passivation will lead only to one of the more stable configurations among a large number of structural isomers. Hence its resulting structural and electronic properties may not exactly represent the corresponding properties of the true ground state configuration of the Si$_n$Ge$_m$ clusters. However this caveat does not affect the main conclusions of our study, including the role played by the lattice mismatch and the surface relaxation in Si$_n$Ge$_m$ clusters with/without hydrogen passivation, and the enhanced radiative transition in Si$_n$Ge$_m$ clusters.

II. METHOD

We considered 71-atom Si$_n$Ge$_m$ clusters, with $m$ taking on the values 0, 18, 35, 53, and 71, respectively. The initial configurations for the five clusters were generated randomly on a regular tetrahedral network. They were then relaxed by the ab initio molecular dynamics scheme developed by Sankey and co-workers (the Fireball scheme) [22]. This scheme is based on the density functional theory (DFT) in the local density approximation (LDA), where a local basis set is used to construct the Kohn-Sham orbitals. The basis functions are slightly excited pseudo-atomic orbitals (PAO). The Kohn-Sham orbitals are calculated self-consistently using the Hamann-Schlüter-Chiang pseudo-potential [23] and
the Ceperley-Alder form of the exchange-correlation potential as parameterized by Perdew and Zunger [24]. We have tested this method in the study of the strain relaxation of Si_{1-x}Ge$_x$ alloys and the results are in good agreement with the experimental observations [25].

In our simulation, $sp^3$-type PAOs were used with confinement radii of 5.0 $a_B$, 5.2 $a_B$, and 3.6 $a_B$ for Si, Ge, and H atoms, respectively. A cubic cell with a lattice constant 50 Å was chosen as the unit cell. This cell size is sufficiently large to ensure that spurious interactions between clusters will vanish. To obtain the stable configuration of a Si$_n$Ge$_m$ or a Si$_n$Ge$_m$H$_{84}$ cluster, molecular dynamics simulations were performed on the clusters, starting from the initial random configuration, at a temperature of $10^3$ K for about 20 ps until the network was equilibrated. The network was then slowly cooled to 300 K for 5 ps, and the dynamical quenching was finally performed to fully relax the system to zero K. Charge transfer was calculated self-consistently in the simulations, which is important in modeling clusters.

After performing the molecular dynamical simulations, we obtained stable configurations, five each for Si$_n$Ge$_m$ and Si$_n$Ge$_m$H$_{84}$ clusters, with the ratio $m/(n+m) = 0.0$, 0.25, 0.51, 0.75, and 1.0, respectively. As an example, Fig. 1 (a) shows the stabilized configuration of the Si$_{36}$Ge$_{35}$ cluster. Apparently, there is strong surface distortion in this case and the stabilized structure is a compact network in a more oblate structure. This kind of structure has also been found to be more stable for the intermediate-size of Si clusters from other theoretical studies [26]. It is found that the surface distortion leads to local bonding configurations with more than four bonds, in particular in the vicinity of the surface. Further structural analysis shows that the average bond lengths of Si-Si ($b_{SiSi}$), Si-Ge ($b_{SiGe}$), and Ge-Ge ($b_{GeGe}$) of the Si$_n$Ge$_m$ clusters are expanded relative to the bulk, as shown in Fig. 2 (a). But they still maintain the relationship of $b_{SiSi} < b_{SiGe} < b_{GeGe}$ and are almost independent of the ratio of $m/(n+m)$. In addition, as shown in Fig. 2 (b), the average angles $\theta_{\alpha\beta\gamma}$, which shows the angle between $\beta\alpha$ and $\beta\gamma$ atoms, are less than the tetrahedral angle, except $\theta_{SiSiSi}$ in Si$_{18}$Ge$_{53}$ cluster. The large fluctuation of the average angles $\theta_{\alpha\beta\gamma}$ as a function of the ratio of $m/(n+m)$ indicates that the clusters have lost their initial tetrahedral symmetry. This means that the surface distortion strongly dominates in the intermediate size Si$_n$Ge$_m$.
clusters, whatever the ratio of Si/Ge.

When the initial configurations were passivated with 84 H atoms to terminate the dangling bonds on the surface atoms, all the relaxed $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters still maintain a tetrahedral symmetry in the interior, with only a minor distortion on the surface. Such features can be seen, for example, from the relaxed structure of $\text{Si}_{36}\text{Ge}_{35}\text{H}_{84}$ shown in Fig. 1(b). The average bond lengths $b_{\text{SiSi}}$, $b_{\text{SiGe}}$, and $b_{\text{GeGe}}$ of the cluster (see Fig. 2(c)) and the average angles $\theta_{\alpha\beta\gamma}$ (see Fig. 2(d)) are quite close to the corresponding features in $\text{Si}_{1-x}\text{Ge}_x$ alloys (comparing Figs. 2(c) and (d) to Figs. 3 and 7 in ref. [25]). This is an indication that the surface distortion in hydrogen-passivated clusters is weak even for $\text{Si}_n\text{Ge}_m\text{H}_l$ clusters of an intermediate size. On the other hand, the mismatch effect becomes the dominating factor in hydrogenated $\text{Si}_n\text{Ge}_m$ clusters, similar to the situation exhibited in $\text{Si}_{1-x}\text{Ge}_x$ alloys [25].

III. ELECTRONIC STRUCTURE

The LDA calculation is known to underestimate the energy gap in the single-particle energy spectrum of semiconductor clusters. Corrections to the underestimated energy gap can be calculated using the GW approach [14, 27, 28]. However, GW calculations are expensive, even for clusters of an intermediate size considered in this work (i.e., $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters with $n + m = 71$). Our main interest in this study is to provide an understanding of the trend of change in the electronic structure and optical properties of $\text{Si}_n\text{Ge}_m$ clusters of a given size as the concentration of the Ge component varies. The LDA approach is expected to be sufficiently accurate to provide a qualitative description of this trend of change. Therefore, we have calculated the electronic density of states (EDOS) of the relaxed $\text{Si}_n\text{Ge}_m$ clusters, using the same DFT/LDA scheme as that in the structural determination.

The EDOSs of $\text{Si}_n\text{Ge}_m$ and $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters at the five ratios of $m/(n + m)$ described previously are shown in Fig. 3. From the left panel of Fig. 3, many defect states associated with the surface distortion were seen in the HOMO-LUMO energy gap region of $\text{Si}_n\text{Ge}_m$ clusters. These defect states were cleared up when the surface was passivated by H atoms (see the right panel of Fig. 3) because H atoms terminate the dangling bonds of the surface atoms, resulting in the clusters keeping the basic tetrahedral symmetry. Even though the
energy spectrum of \( \text{Si}_n\text{Ge}_m \) and that of \( \text{Si}_n\text{Ge}_m\text{H}_{84} \) clusters are quite different, the general feature of the energy spectrum in both cases was found to be rather insensitive to the ratio of \( m/(n + m) \).

Fig. 4 (a) and (b) illustrate the HOMO-LUMO energy gap of \( \text{Si}_n\text{Ge}_m \) and \( \text{Si}_n\text{Ge}_m\text{H}_{84} \) clusters as a function of the ratio of \( m/(n + m) \), respectively. Because of the existence of the defect states in the energy gap region, the HOMO-LUMO gap of \( \text{Si}_n\text{Ge}_m \) clusters is small (only 0.4-0.5 eV) and does not show any dependence on the ratio of Si to Ge. But the HOMO-LUMO gap of the hydrogenated \( \text{Si}_n\text{Ge}_m \) clusters is opened up to several eV (3.5 - 4.0 eV) and shows a linear dependence on the ratio of Si to Ge which reflects the mismatch effect similar to that for the corresponding alloys [25]. Specifically, experimental observation [29] and theoretical calculations [30, 31] indicate that the lattice mismatch associated with alloying in \( \text{Si}_{1-x}\text{Ge}_x \) alloys induces a change of the conduction band, in particular, the lowest energy in the conduction band (LUMO) changes from the \( \Delta \) point near X point for Si-rich alloys to the L point for Ge-rich alloys [31], leading to a nearly linear decrease of the indirect band gap. In the case of \( \text{Si}_n\text{Ge}_m \) clusters passivated by hydrogen, the dominating factor is again the lattice mismatch. This similar effect is observed from the HOMO-LUMO gap as shown in Fig. 4(b). The existence of such large energy gap for \( \text{Si}_n\text{Ge}_m \) clusters of this size (with \( n + m = 71 \)) can be attributed to the effect of quantum confinement and is consistent with the scenario of a blueshift in PL.

IV. OPTICAL PROPERTIES

It is well known that an accurate calculation of the band gap is important for the determination of the optical polarizability of semiconductors and insulators. Many efforts have been focused on the correction to the "too-small" band gap obtained by DFT/LDA calculations for the purpose of accurately predicting the optical response of these systems. Another key factor for determining the optical properties of these systems is a proper description of interacting electron-hole pairs (excitons). While calculations using the Green’s function based on the GW approach have led to quite accurate prediction of the energy of low-lying excitations and the oscillator strength for small clusters [32], the application of this method to clusters of intermediate sizes is still computationally too expensive. Most recently, a
method based on the linear-response theory within the frame work of the time-dependent (TD) DFT/LDA had been applied to calculate the optical spectra of clusters \[13\] with results in general agreement with experimental results as well as more complicated theoretical methods (e.g., GW approach). However, at present, the application of the method is still limited to clusters of radius less than 1 nm.

The study of the dielectric function via the optical transition matrix elements allows us to obtain information directly on absorption and photoluminescence spectra. It can also allow us to obtain information indirectly on the relevant radiative PL processes. The imaginary part of the dielectric function can be calculated by \[32\]

\[
\text{Im}\varepsilon(\omega) = \frac{16\pi e^2}{\omega^2} \sum_S |\mathbf{e} \cdot <0|\mathbf{v}|S>|^2 \delta(\omega - \Omega_S)
\]  

(1)

where \(\mathbf{e}\) is the polarization vector of the light, \(\mathbf{v} = i/\hbar[H, r]\), \(|0\rangle\) refers to the ground state, \(|S\rangle\) the excited state, and \(\Omega_S\) the excitation angular frequency. The excited state can be expanded in electron-hole pair configuration such that

\[
|S\rangle = \sum_v \sum_c A_{vc}^S |vc\rangle
\]  

(2)

The coupling coefficient \(A_{vc}^S\) can be calculated within the framework of the two-particle Green’s function by solving the corresponding Bethe-Salpeter equation. A reasonable approximation leads to the determination of \(A_{vc}^S\) as the positive solutions to the eigenvalue equation \[32\].

\[
(E_c - E_v)A_{vc}^S + \sum_{v',c'} K_{vc,v'c'}^{AA}(\Omega_S)A_{v'c'}^S = \Omega_S A_{vc}^S
\]  

(3)

where \(E_c\) is the single-electron energy in the conduction band, \(E_v\) the single-electron energy in the valence band, and \(K_{vc,v'c'}^{AA}\) the electron-hole interaction kernel. The most computationally intensive part in the calculation is the evaluation of the electron-hole interaction kernel \(K_{vc,v'c'}^{AA}\). This bottleneck is one of the main culprits that limits the application of the GW approach to only very small clusters and that of the TDLAD to clusters with the radius less than 1 nm.
Using Eq. (2), the optical transition matrix elements can be written as

\[ < 0|v|S> = \sum_v \sum_c A_{vc}^S < v|v|c > \]  

(4)

The substitution of Eq. (4) into Eq. (1) shows that the imaginary part of the dielectric function depends on the transition matrix elements of electron-hole pair configuration \( < v|v|c > \) as well as the coupling coefficient \( A_{vc}^S \). For clusters \( \text{Si}_n\text{Ge}_m \) of a given size \( (n + m=\text{constant}) \), the changing composition is expected to affect more on the transition matrix elements \( < v|v|c > \) than on the coupling coefficient \( A_{vc}^S \) because of the insensitivity of the EDOSs to the change in configuration (see Eq. (3) and Fig. 3). Since the main interest of this work is to understand the effect on the optical properties of \( \text{Si}_n\text{Ge}_m \) clusters of a given intermediate size \( (n + m=\text{constant}) \) by incorporating Ge atoms into the cluster, we therefore focus our attention on the effect on \( < v|v|c > \) due to the change in the composition in \( \text{Si}_n\text{Ge}_m \) clusters, particularly on how the change in \( < v|v|c > \) affects the radiative transition probability of the clusters as its composition varies.

To set up a benchmark for the analysis of the trend of the optical features of \( \text{Si}_n\text{Ge}_m \) clusters of a given size but varying compositions within the framework considered in this work, we have calculated the imaginary part of the dielectric function without the electron-hole interaction. In this situation, Eq. (1) reduce to

\[ \text{Im}\epsilon(\omega) = \frac{16\pi^2 e^2}{V} \sum_v \sum_c |< v|r \cdot \hat{e}|c >|^2 \delta(E_c - E_v - \hbar\omega) \]  

(5)

Here the sums are over all the eigenstates \( |v > \) and \( |c > \). \( \mathbf{r} \) is the position operator, and \( V \) the volume of the cluster. Specifically, we calculated the average \( \text{Im}\epsilon(\omega) \) \( (= \frac{16\pi^2 e^2}{V} \sum_v \sum_c \frac{1}{3}(|< v|x|c >|^2 + |< v|y|c >|^2 + |< v|z|c >|^2)\delta(E_c - E_v - \hbar\omega)) \) since the shapes of the relaxed \( \text{Si}_n\text{Ge}_m \) clusters are compact and suggesting a more-or-less isotropic behavior.

Fig. 5 presents the calculated \( \text{Im}\epsilon(\omega) \) at various ratios of Si to Ge in the cases with and without H-passivation. It is found that the optical gaps, defined by the onset energy of the spectra edge in \( \text{Si}_n\text{Ge}_m \) clusters, are in the range of 0.4-0.5 eV and are almost independent of the ratio of Si to Ge. The optical spectral peaks are smooth and broad. The spectra display low-energy transitions and show a tail near the optical edge. The tail corresponds to
the defect states due to the surface distortion as shown in EDOS of Si\textsubscript{n}Ge\textsubscript{m} clusters (Fig. 3). Therefore, such optical properties are not suitable for the application as optical devices. The optical gaps of H-terminated Si\textsubscript{n}Ge\textsubscript{m} clusters, however, are in the range of 3.3-4.1 eV and have a linear dependence on the ratio of Si to Ge. Unlike optical spectra of Si\textsubscript{n}Ge\textsubscript{m} clusters, the spectral peaks of hydrogenated Si\textsubscript{n}Ge\textsubscript{m} clusters are sharp with no tail at the edge of the optical spectra. Such peaks near the edge reflect the high structural symmetry (the tetrahedral symmetry in the present study) of the Si\textsubscript{n}Ge\textsubscript{m}H\textsubscript{84} clusters. The large optical gaps in Si\textsubscript{n}Ge\textsubscript{m}H\textsubscript{84} clusters indicate the possibility of optical applications.

Since the luminescence is a result of significant overlap in electron and hole wave functions, and the strength of the luminescence depends on the extent of this overlap and the transition probability, we investigated the radiative transition probabilities of Si\textsubscript{n}Ge\textsubscript{m} and Si\textsubscript{n}Ge\textsubscript{m}H\textsubscript{84} clusters. The state-to-state spontaneous transition probability (\(W_{ij}\)) (the inverse of the radiative lifetime \(\tau_{ij}\)) of the first-order radiative process between states \(|i>\) and \(|j>\) is defined from the Fermi golden rule and is given by [33]

\[
W_{ij} = \frac{1}{\tau_{ij}} = \frac{4e^2\omega_{ij}^3n}{3hc^3} |< i| \mathbf{r} \cdot \hat{\mathbf{e}} |j>|^2
\]  

(6)

where \(e\) and \(m\) are the electron charge and mass, respectively. \(c\) the speed of light, \(\omega_{ij}\) the energy difference (divided by \(h\)) between states \(|i>\) and \(|j>\), and \(n\) the refractive index of Si\textsubscript{n}Ge\textsubscript{m} clusters. From ellipsometry [34] and optical-absorption [3] experiments for porous Si, it seems that the refractive index decreases with increasing porosity. Since there is no measurement of the refractive index for Si\textsubscript{n}Ge\textsubscript{m} clusters, we choose \(n\) to be 1 in the present calculation.

It is apparently from the formula of \(W_{ij}\) that the energy difference \(\omega_{ij}^3\) as well as the dipole matrix elements \(<i|\mathbf{r}|j>\) dominate the spontaneous transition probability. Table I lists the HOMO-LUMO spontaneous emission probabilities \(W_{HL} (= \frac{4e^2\omega_{HL}^3n}{3hc^3} |< H|x|L>|^2 + |< H|y|L>|^2 + |< H|z|L>|^2)\) of Si\textsubscript{n}Ge\textsubscript{m} and Si\textsubscript{n}Ge\textsubscript{m}H\textsubscript{84} clusters. It can be seen that \(W_{HL}\)'s for Si\textsubscript{n}Ge\textsubscript{m} clusters are very small (\(\approx 10^{-5}\) in ns\(^{-1}\)). The corresponding radiative lifetime \(\tau_{HL}\) are quite large, i.e. 608 \(\mu\)s for Si\textsubscript{71}, 49 \(\mu\)s for Si\textsubscript{53}Ge\textsubscript{18}, 71 \(\mu\)s for Si\textsubscript{36}Ge\textsubscript{35}, 25 \(\mu\)s for Si\textsubscript{18}Ge\textsubscript{53}, and 121 \(\mu\)s for Ge\textsubscript{71}, respectively. But the HOMO-LUMO spontaneous transition probabilities \(W_{HL}\) of hydrogenated Si\textsubscript{n}Ge\textsubscript{m} clusters are about two to three orders of magnitude larger than the corresponding ones of Si\textsubscript{n}Ge\textsubscript{m} clusters. Their corresponding
radiative lifetime $\tau_{HL}$ are therefore shortened by about two to three orders, \textit{i.e.}, 8.1 $\mu$s for Si$_{71}$H$_{84}$, 0.12 $\mu$s for Si$_{53}$Ge$_{18}$H$_{84}$, 0.059 $\mu$s for Si$_{36}$Ge$_{35}$H$_{84}$, 0.07 $\mu$s for Si$_{18}$Ge$_{53}$H$_{84}$, and 0.098 $\mu$s for Ge$_{71}$H$_{84}$, respectively. The large differences in $W_{HL}$ and $\tau_{HL}$ between Si$_n$Ge$_m$ and Si$_n$Ge$_m$H$_{84}$ clusters are mainly due to the energy differences of $\omega^3_{HL}$ between HOMO-LUMO states in Si$_n$Ge$_m$ and Si$_n$Ge$_m$H$_{84}$ clusters. As seen in Fig. 3, the HOMO-LUMO energy differences $\omega_{HL}$ of Si$_n$Ge$_m$H$_{84}$ clusters are about 10 times larger than those of Si$_n$Ge$_m$ clusters.

It is noted that the radiative lifetime $\tau_{HL}$ calculated for Si$_{71}$H$_{84}$ cluster (8.1 $\mu$s) is comparable to that of Si$_{66}$H$_{64}$ cluster of a similar size (6 $\mu$s) obtained by Hirao \textit{et al.} [33]. The spontaneous transition probabilities $W_{HL}$ of Si$_{71}$H$_{84}$ cluster ($0.012 \times 10^4$ ms$^{-1}$) is also consistent with the recombination rate of an excited electron-hole pair in Si crystallites (about $10^4$ ms$^{-1}$) for the photon energy of 4.0 eV at 5 K calculated by Delerue \textit{et al.} [6, 10]. The spontaneous transition probabilities $W_{HL}$ is found in our calculation to be higher in pure Ge$_{71}$H$_{84}$ cluster ($1.01 \times 10^{-2}$ ns$^{-1}$) than in pure Si$_{71}$H$_{84}$ cluster ($0.012 \times 10^{-2}$ ns$^{-1}$). This result is qualitatively consistent with the results of the radiative decay rate of excitons in Ge quantum dots (about $0.2 \times 10^{-2}$ ns$^{-1}$) and in Si quantum dots (about $0.05 \times 10^{-2}$ ns$^{-1}$) with the dot radius of 10 Å obtained by Takagahara \textit{et al.} [20].

Our analysis of the radiative transition in Si$_n$Ge$_m$ clusters indicates that the HOMO-LUMO spontaneous emission probability $W_{HL}$ (radiative life time $\tau_{HL}$) of Si$_n$Ge$_m$ and Si$_n$Ge$_m$H$_{84}$ clusters is very sensitive to the Ge content ($m/(n+m)$) in the cluster. Table I shows a sudden and substantial increase in $W_{HL}$ once Ge atoms are incorporated into the Si clusters. In particular for hydrogen-passivated Si$_n$Ge$_m$H$_{84}$ clusters, the incorporation of Ge atoms into the Si cluster can bring about a dramatic increase in $W_{HL}$ of up to two orders of magnitude as compared to the pure hydrogen-passivated Si cluster. An increase in $W_{HL}$ of this magnitude for Si$_n$Ge$_m$H$_{84}$ with $n + m = 71$ suggests that the incorporation of Ge atoms into hydrogen-passivated Si clusters may pave the way to dramatically enhance the optical properties of pure Si clusters.

To shed light on the underlying physics of this dramatic change in the HOMO-LUMO spontaneous emission probability $W_{HL}$, we carried out a detailed analysis of factors that might affect $W_{HL}$. From Eq. (6), it can be seen that $W_{HL}$ is controlled by the interplay between the HOMO-LUMO gap $\omega_{HL}$ and the dipole matrix-element $<H|r|L>$. As shown in Fig. 4, $\omega_{HL}$ for Si$_n$Ge$_m$ clusters of a given size does not exhibit any sensitive dependence
on the Ge content. For $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters, $\omega_{HL}$ decreases with increasing Ge content ($m/(n+m)$) and shows a linear dependence on the Ge content. However, the range of variation for $\omega_{HL}$ is only by a factor of $\sim 1.22$. On the other hand, the dependence of the dipole matrix element on $m/(n+m)$ shows a more complicated pattern (see Table II). For example, $|<H|r|L>|^2 = \frac{1}{3}(|<H|x|L>|^2 + |<H|y|L>|^2 + |<H|z|L>|^2)$ for $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters shows a dramatic increase of two orders of magnitude once Ge atoms are incorporated into the Si cluster. It peaks at the equal composition of Si and Ge atoms, and then reduces to a smaller but same order of magnitude for the pure Ge cluster. Since the range of variation for $|<H|r|L>|^2$ (over two orders of magnitude) far surpasses that for $\omega_{HL}^3$ (less than one order of magnitude), it must be the behavior of $|<H|r|L>|^2$ that determines the pattern of behavior for $W_{HL}$. As shown in Table I, $W_{HL}$ for $\text{Si}_n\text{Ge}_m\text{H}_{84}$ clusters indeed exhibits a similar pattern as that of $|<H|r|L>|^2$, namely, a drastic, almost two orders of magnitude, increase for small Ge content, peaking at an equal composition of Si and Ge atoms, reducing to a somewhat smaller value for the pure hydrogen-passivated Ge cluster.

To shed light on the mechanism responsible for the dramatic increase in $|<H|r|L>|^2/W_{HL}$ once Ge atoms are incorporated into the hydrogen-passivated Si clusters, we express the dipole matrix element in terms of the pseudo-atomic orbitals within the Fireball scheme [22], namely,

$$<H|r|L> = \sum_{i\alpha,j\beta} (c_{i\alpha}^H)^* c_{j\beta}^L <i\alpha|r|j\beta> \quad (7)$$

where $c_{i\alpha}^\lambda$ denotes the coefficient of expansion of the wave function $\lambda$ in the pseudo-atomic orbital $\alpha$ at the site $i$. The matrix element $<i\alpha|r|j\beta>$ depends only on the structural configuration of the cluster. Specifically

$$<i\alpha|r|j\beta> = \int \phi_{i\alpha}^*(r-R_i)r\phi_{j\beta}(r-R_j)dr$$

$$= \int \phi_{i\alpha}^*(r')r'\phi_{j\beta}(r'-R_{ij})dr' + R_i \int \phi_{i\alpha}^*(r')\phi_{j\beta}(r'-R_{ij})dr' \quad (8)$$

where $\phi_{i\alpha}(r-R_i)$ is the pseudo-atomic orbital $\alpha$ centered at atomic site $i$, $R_i$ is the position vector of atomic site $i$, $R_{ij} = R_j - R_i$, and $r' = r - R_i$, respectively.

Since there is no substantial structural change for hydrogen-passivated $\text{Si}_n\text{Ge}_m\text{H}_l$ clusters of a given size ($n+m=$constant), Eqs. (7) and (8) then indicate that the coefficients of
expansion of the HOMO and LUMO states play the most significant role in determining $<H|\mathbf{r}|L>$. In Fig. 6, we plot the absolute value of the coefficient $c^\lambda_{i\alpha}$ for the pseudo-atomic orbital $\phi_{\alpha}(\mathbf{r} - \mathbf{R}_i)$ vs atomic site $i$ for the HOMO and LUMO states of hydrogen-passivated Si$_n$Ge$_m$H$_{84}$ ($n + m = 71$) clusters with various Ge content. When the patterns of behavior for the hydrogen-passivated pure Si cluster (Si$_{71}$Ge$_0$H$_{84}$) are compared with those of the hydrogen-passivated pure Ge cluster (Si$_0$Ge$_{71}$H$_{84}$), it can be seen that the HOMO state for the two clusters shows similar distribution. However, there is a striking difference between the patterns exhibited by the LUMO states of the two clusters. In the case of the pure Si cluster, the expansion coefficients of the $p_x$-orbital give the major contribution to the LUMO states. On the other hand, two outstanding features differentiate the pattern of the LUMO state of the pure Ge cluster from that of the pure Si cluster: (1) The expansion coefficients of the $s$-orbital give the major contribution to the LUMO state. (2) The magnitude of the coefficients of the $s$-orbital is greater than those of the $p_x$-orbital for the pure Si cluster by a factor of 2 to 3. An examination of other figures in Fig. 6 shows that the LUMO state possesses the same two features as long as the cluster has a Ge content and these features appear mostly at the Ge sites. The overlap between a $s$-orbital and neighboring orbitals is far less restrictive as compared to that between a $p_x$ orbital with its neighboring orbitals. This fact, together with the more pronounced strength of the coefficients for the $s$-orbital in the LUMO state of Ge-containing clusters, leads to a stronger overlap between the LUMO and HOMO states of Ge-containing clusters, thus explaining the correlation between the appearance of these two features and the sudden and dramatic increase in the value of $|<H|\mathbf{r}|L>|^2$ once Ge atoms are incorporated into the hydrogen-passivated Si clusters. This correlation also indicates that these two features are mainly responsible for the sudden and dramatic increase in $W_{HL}$ once the hydrogen-passivated Si cluster possesses a Ge content.

Finally, it should be noted that the properties of the HOMO state are closely related to the effective mass of heavy holes while those of the LUMO state to the average effective mass of electrons. The mass of the heavy hole for bulk Si is reasonably close to that for bulk Ge. On the other hand, the average effective mass of electrons for bulk Ge is a factor of 2 smaller than that for bulk Si. It is therefore tempting to speculate that the behavior patterns of HOMO and LUMO states are related to the sameness of the mass of heavy hole and the difference in the effective mass of electron for Si and Ge, respectively. One may also
add that the fact that the effective mass of Ge is two times smaller than that of Si could be the contributing factor for the dominant contribution of the s-orbital in the LUMO state for clusters with a Ge content.

V. CONCLUSION

The findings of our systematic study of the structural, electronic, and optical properties of Si$_n$Ge$_m$ cluster with/without hydrogen passivation include: (1) There is only a weak surface distortion in hydrogen-passivated clusters Si$_n$Ge$_m$H$_l$ of intermediate sizes. The mismatch effect is then the dominating factor in determining properties of those clusters. (2) The HOMO-LUMO gap for Si$_n$Ge$_m$H$_l$ clusters of intermediate sizes opens up to several eVs, consistent with a blueshift in PL. It shows a linear dependence on the ratio $n/(n + m)$ ($n + m = \text{constant}$) similar to the pattern exhibited by Si$_{1-x}$Ge$_x$ alloys [25]. (3) The HOMO-LUMO spontaneous emission probability $W_{HL}$ of Si$_n$Ge$_m$H$_l$ clusters is very sensitive to the Ge content in the cluster. Once Ge atoms are incorporated into the cluster, it can bring about a two-order of magnitude increase in $W_{HL}$. Our analysis attributes this dramatic increase to the strong overlap between HOMO and LUMO states around Ge atoms. Our findings therefore suggest that hydrogen-passivated Si$_n$Ge$_m$ clusters may be a viable candidate as components in optical devices.

FIG. 1: The stabilized structure of Si$_{36}$Ge$_{35}$ cluster shows a compact shape (a) and that of Si$_{36}$Ge$_{35}$H$_{84}$ cluster shows a spherical-like shape with the tetrahedral symmetry in the interior part (b). The Si atoms are marked by the dark grey color, Ge by the black one, and H by the light grey one.

FIG. 2: The average bond lengths of $b_{\text{SiSi}}$, $b_{\text{SiGe}}$, and $b_{\text{GeGe}}$ in Si$_n$Ge$_m$ clusters (a) and in Si$_n$Ge$_m$H$_{84}$ clusters (c) as a function of the ratio of $m/(n + m)$. The average angles $\theta_{\alpha\beta\gamma}$, the angle between two bonds $\beta\alpha$ and $\beta\gamma$ in Si$_n$Ge$_m$ clusters (b) and in Si$_n$Ge$_m$H$_{84}$ clusters (d) as a function of the ratio $m/(n + m)$ are shown in the right side of the panel. The dotted lines in (b) and (d) are the tetrahedral angle of 109.47 degree in the bulk Si and Ge.

FIG. 3: The electronic densities of states of Si$_n$Ge$_m$ clusters (left column) and Si$_n$Ge$_m$H$_{84}$ clusters (right column) at various ratio of $m/(n + m)$. The Fermi levels are denoted by the vertical bars and the broaden is 0.05 eV.

FIG. 4: The HOMO-LUMO energy gap of Si$_n$Ge$_m$ clusters (a) and Si$_n$Ge$_m$H$_{84}$ clusters (b) as a function of the ratio of $m/(n + m)$.

FIG. 5: The averaged imaginary part of the dielectric functions calculated from Eqs. (5) of Si$_n$Ge$_m$ clusters (left column) and Si$_n$Ge$_m$H$_{84}$ clusters (right column) at various ratio of $m/(n + m)$. The broaden is 0.05 eV.
FIG. 6: The absolute value of the coefficient $c_{\lambda i}^\alpha$ vs the pseudo-atomic orbital $\alpha$ centered at atomic site $i$ for the HOMO (left column) and LUMO states (right column) of Si$_n$Ge$_m$H$_{84}$ clusters. The numbers labeled at x axis denote the number of atomic site. At each atomic site, there are four histograms corresponding to the pseudo-atomic orbital $\alpha$. The order of pseudo-atomic orbital $\alpha$ is $s, p_x, p_y$, and $p_z$, from left to right, respectively.

The diagram shows the absolute value of the coefficient $c_{\lambda,i}$ for pseudo-atomic orbitals at different sites. The x-axis represents the number of the pseudo-atomic orbital $\alpha$ at site $i$, while the y-axis represents the absolute value of the coefficient $c_{\lambda,i}$. The labels $\lambda = \text{HOMO}$ and $\lambda = \text{LUMO}$ correspond to the highest occupied and lowest unoccupied molecular orbitals, respectively.

Specifically:
- $\lambda = \text{HOMO}$ for $\text{Si}_{71}\text{H}_{84}$
- $\lambda = \text{LUMO}$ for $\text{Si}_{71}\text{H}_{84}$
- $\lambda = \text{HOMO}$ for $\text{Si}_{53}\text{Ge}_{18}\text{H}_{84}$
- $\lambda = \text{LUMO}$ for $\text{Si}_{53}\text{Ge}_{18}\text{H}_{84}$
- $\lambda = \text{HOMO}$ for $\text{Si}_{36}\text{Ge}_{35}\text{H}_{84}$
- $\lambda = \text{LUMO}$ for $\text{Si}_{36}\text{Ge}_{35}\text{H}_{84}$
- $\lambda = \text{HOMO}$ for $\text{Si}_{18}\text{Ge}_{53}\text{H}_{84}$
- $\lambda = \text{LUMO}$ for $\text{Si}_{18}\text{Ge}_{53}\text{H}_{84}$
- $\lambda = \text{HOMO}$ for $\text{Ge}_{71}\text{H}_{84}$
- $\lambda = \text{LUMO}$ for $\text{Ge}_{71}\text{H}_{84}$
