Abstract

**Purpose:** Although DNA repair mechanism is a key to prevent carcinogenesis, its activation in established cancer cells may support their proliferation and aggravate cancer progression. RAD51 cooperates with BRCA2 and is essential in the homologous recombination of DNA repair. To this end, we hypothesized that RAD51 gene expression is associated with cancer cell proliferation and poor prognosis of breast cancer (BC) patients.

**Methods:** A total of 8515 primary BC patients with transcriptome and clinical data from 17 independent cohorts were analyzed. Median was used to divide each cohort into high and low RAD51 expression groups.

**Results:** High RAD51 expression enriched DNA repair gene set and was correlated with DNA repair-related genes. Nottingham histological grade, Ki67 expression and cell proliferation-related gene sets (E2F Targets, G2M Checkpoint and Myc Targets) were all significantly associated with the high RAD51 BC. RAD51 expression was positively correlated with Homologous Recombination Deficiency, as well as both mutation burden and neoantigen that accompanied with higher infiltration of immune cells. Primary BC with lymph node metastases were associated with high expression of RAD51 in 2 cohorts. There was no strong correlation between RAD51 expression and drug sensitivity in cell lines, and RAD51 expression was lower after the neoadjuvant chemotherapy compared to before the treatment. High RAD51 BC was associated with poor prognosis consistently in 3 independent cohorts.

**Conclusion:** RAD51 gene expression is associated with aggressive cancer biology, cancer cell proliferation, and poor survival in breast cancer.

Introduction

Homologous recombination repair is a major DNA repair mechanism for DNA double-strand breaks caused by various external or internal stress [1]. Since *BRCA1* and *BRCA2* genes are essential for homologous recombination repair [2], it is well known that mutations in germline *BRCA1* and/or *BRCA2* induce genomic instability due to homologous recombination deficiency (HRD), leading to an increased risk of breast and/or ovarian carcinogenesis [2]. HRD is not only an important cause of hereditary breast cancer but also contributes to “BRCA-ness”, which are the traits of *BRCA1* genetic disorder found in some sporadic breast cancers [3–5]. HRD is a critical therapeutic target in breast cancer because nearly 70% of the most aggressive triple negative breast cancer (TNBC) subtype contain characteristic “BRCA-ness” features [6]. Since poly ADP-ribose polymerase (PARP) is also essential in DNA repair, PARP inhibitors induce DNA double-strand breaks and destroy cancer cells with HRD. Effectiveness of PARP inhibitors against breast cancer with germline BRCA mutation were confirmed in multiple clinical trials [7–9].

RAD51 is an ATPase that forms helical nucleoprotein filaments on single or double-stranded DNA [10] and plays a critical role in the early stages of DNA double-strand break recognition in homologous recombination repair. BRCA2 activates the homologous recombination cascade in a RAD51-dependent
manner, particularly during mitosis [11]. BRCA2 recognizes nuclear filament in single strand DNA loaded with RAD51 during DNA damage and invade the homologous DNA duplex to pair up and initiate homologous recombination repair [12, 13]. Although RAD51 expression is tightly regulated in normal cells to avoid aberrant DNA recombination [14], its expression is strongly upregulated in several types of cancer including breast [15-18]. High levels of RAD51 over-activate homologous recombination, resulting in uncontrolled double-strand breaks repair and cancer cell persistence [19]. Therefore, high expression of RAD51 confers resistance to radiation and several drugs inducing double-strand breaks to cancer cell [20-22]. Based on these mechanisms, some reported the involvement of RAD51 in cancer resistance to PARP inhibitor [23, 24]. Some even suggested RAD51 to be a candidate of a biomarker of drug sensitivity and as a therapeutic target to avoid drug resistance.

We have been pursuing translational research that addresses the clinical relevance of a gene expression using in silico analysis of large patient cohorts with transcriptomes associated with clinical parameters [25-32]. Previously, we reported that increased expression of BRCA2 gene is associated with enhanced cancer cell proliferation and immunogenicity in breast cancer [33]. In cancer cells, high expression of BRCA2 correlated with HRD and was also associated with an aggressive trait of breast cancer. Given that RAD51 acts together with BRCA1 and/or BRCA2 as a key player in homologous recombination repair, we hypothesized that RAD51 mRNA expression is associated with increased cancer cell proliferation, and thus with poor prognosis. In addition, for the above reasons, we thought that RAD51 might be highly expressed in the treatment non-responder group due to its involvement in drug resistance. To date, studies of RAD51 have been limited to experiments with cell lines and animals and retrospective studies with small cohorts, but in this study, we analyzed the relationship between RAD51 gene expression and breast cancer using three large primary breast cancer cohorts of several thousand patients. In addition, we analyzed RAD51 expression by treatment response using multiple neoadjuvant chemotherapy (NAC) treated breast cancer cohorts to explore its potential as a predictor and biomarker of treatment response in breast cancer.

**Methods**

**Patient data acquisition**

All cohorts were downloaded in September 2021. A total of 8515 patients were included in the analysis. Clinicopathological factors and mRNA sequencing data for 1077 breast cancer patients of the Cancer Genome Atlas (TCGA) were downloaded from cBiopotal [34–36]. Batch-normalized RNA sequencing data from Illumina HiSeq_RNASeqV2 to HUGO symbols were used with log2 conversion. We also downloaded the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC) cohort [37] of 1904 breast cancer from cBiopotal and microarray RNA expression data annotated from illumina Human v3 to HUGO symbols was used. GSE96058 is a validation cohort of 3069 breast cancer patients from the Sweden Cancerome Analysis Network - Breast study that assessed the genomic profile of early breast cancer [38]. Clinicopathological factors for GSE96058 were downloaded using the R package GEOquary and RNA sequence data annotated with the HUGO symbol were downloaded directly from NCBI Gene.
Expression Omnibus database [39]. For neoadjuvant chemotherapy response following primary breast cancer cohorts were analyzed: GSE21974 [40], GSE28844 [41], GSE114403 [42], GSE87455 [43, 44], GSE25066 [45, 46], GSE50948 [47], GSE20271 [48, 49], GSE20194 [50, 51], GSE180962 [52], GSE22358 [53], GSE22226 [54], GSE163882 [55], GSE34138 [56, 57], and GSE16446 [58]. These cohorts were downloaded from the GEO database via the R package GEOquary as well. For GSE180962, only the control group was used in the analysis. The expression of RAD51 was calculated from the mean value of probes assigned to RAD51 from the platform corresponding to each expression data series. Details of the treatment information, the number of patients included in the study, the access number of the platform used for annotation for each cohort are summarized in Supplementary Table 1 and 2.

**Breast cancer cell line RAD51 expression and drug sensitivity data**

Breast cancer cell line RNA sequence data and drug susceptibility data were obtained from the Depmap portal, as we reported previously [59, 60]. This included 64 breast cancer cell lines, and immunohistochemistry staining data were downloaded as well. Expression 21Q3 Public data was used for RAD51 expression and AUC data from PRISM primary or secondary screening, GDSC1, and GDSC2 data was used to determine drug sensitivity.

**Gene Set Enrichment Analysis**

Gene Set Enrichment Analysis (GSEA) [61] was performed on the gene expression data by dividing the analysis dataset into two groups based on the median expression of RAD51. This approach is one of gene function analyses examines how strongly pathways defined by particular genes are expressed between two sets. GSEA 4.1.0, free software from Broad Institute, was used for the analysis and Hallmark was selected as the gene set from the major collection of the Molecular Signatures Database [62]. Following the recommendations of the Broad Institute, FDR q-values below 25% were used as cut-off values for significance, and the Normalized Enrichment Score (NES) was used to assess the strength of the correlation with the gene set.

**Immune cell fractionation and HRD and mutation score analysis**

TCGA HRD score, intratumoral heterogeneity score, mutation burden score, and immune activity score were calculated and reported by Thorsson et al. in 2018 [63]. Fractionation of intratumoral immune cells and stromal cells was calculated using the xCell web tool [64], an algorithm for enumerating immune cell subsets from the transcriptome, as previously reported [65–67]. xCell estimates immune cell fraction for each cohort by comparing 489 gene signatures corresponding to 64 cell types, including adaptive and innate immune cells, hematopoietic progenitor cells, epithelial cells, and extracellular matrix cells, with the input of bulk gene expression dataset. CYT score was used as a measure of immune activity, as previously reported [67, 68].

**Statistical analysis**
Data downloading, organization, analysis, and visualization were done using R 4.0.1. The following packages were used in this study: Survival 3.2-11, survAUC 1.0-5, S4Vectors 0.30. 0, MatrixGenerics 1.4.3, Biobase 2.52.0, grayzoneSurv 1.0, RcmdrPlugin.EZR 1.54, RcmdrMisc 2.7-1. ggplot2 3.3.5, backports 1.2.1, tidyverse 1.3.1, GEOquery 2.60.0, SummarizedExperiment 1.22.0. Median values were used for all cut-offs for comparisons between high and low RAD51 groups. All p-values were calculated by a two-sided test and the cut-off for statistical significance was set at 0.05.

Results

RAD51 gene expression was associated with DNA repair activity in breast cancer

RAD51 is known to play an essential role in the DNA repair mechanism. Therefore, we first investigated whether RAD51 gene expression was associated with the DNA repair pathway and with expressions of its member gene. Comparison of RAD51 expression between normal breast and tumor tissues in the TCGA cohort showed that RAD51 was highly expressed in breast cancer (p<0.001, Figure1a). Intratumoral heterogeneity and Homologues Recombination Deficiency (HRD) scores were positively correlated with RAD51 expression in TCGA (r=0.32 and 0.53, respectively. Figure1b). Further, RAD51 high breast cancer significantly enriched the DNA repair gene set consistently in TCGA, METABRIC, and GSE96058 cohorts (All p<0.001 and FDR<0.01, Figure1c), and it was associated with high expression of DNA repair genes, such as BRCA1, BRCA2, E2F1, E2F4, E2F7, and CDK12, consistently in all three cohorts (TCGA, METABRIC, and GSE96058. All p<0.05. Figure1c). To this end, we found that RAD51 expression is associated with DNA repair activity in the breast cancer tumor microenvironment (TME).

RAD51 gene expression was strongly associated with cancer cell proliferation

Since cancer with HRD is known to be highly malignant, we next investigated the relationship between RAD51 expression and cancer cell proliferation. Utilizing the score value provided by Thorsson et. al. [63], we found a very strong correlation between RAD51 expression and the Proliferation score in the TCGA cohort (r=0.879, p<0.001, Figure2a). RAD51 expression strongly correlated with Nottingham histological grades, pathological quantification of cancer cell proliferation, consistently in all three cohorts, TCGA, METABRIC, and GSE96058 (all p<0.001, Figure2b). In agreement, RAD51 expression was highly correlated with MKI67, which is a cell proliferation marker gene, consistently in all three cohorts (all r>0.4, Figure2b). Strikingly, all five of the cell proliferation-related gene sets in the Hallmark collection (E2F Targets, G2M Checkpoint, Myc Targets v1 and v2, and Mitotic Spindle) and MTORC1 Signaling were enriched in high-RAD51 breast cancer group consistently in all cohorts with a strong significance of FDR<0.01 (Figure2c). These results consistently suggested that high RAD51 breast cancer is associated with high cancer cell proliferation.
RAD51 was associated with a high mutation rate

Since RAD51 mainly co-acts with BRCA2 and partly with BRCA1, it was of interest to investigate whether RAD51 expression was associated with overall mutation rates and BRCA gene mutations. Silent or Non-silent mutation rates were significantly increased in the high RAD51 expression breast cancer group in the TCGA (both p<0.001, Figure3a). In addition, we compared wild type to mutation in BRCA1, BRCA2, or in both. RAD51 expression was significantly higher in patients with mutation in BRCA1, BRCA2, or in both in the METABRIC cohort (all p<0.01). However, this was not validated in the TCGA cohort (Figure3b). To this end, RAD51 expression correlated with cancer mutation level but not consistently with BRCA mutations.

RAD51 high breast cancer were immunogenic and elicited cancer immunity in the cancer microenvironment

We have previously reported that cancers with high mutation rates elicit immunogenicity and specifically cancer immunity. Having identified high levels of mutation in high RAD51 breast cancers, it was of interest to investigate the association of RAD51 expression with cancer immunity. As expected, single-nucleotide variant (SNV) neoantigens and Indel neoantigens were both significantly higher in breast cancer with high RAD51 expression. Several factors related to cancer immunity (interferon (IFN)-gamma response, tumor infiltrating lymphocytes (TIL) regional fraction, Wound Healing, B-Cell Receptor (BCR) Richness, BCR Shannon, and Fraction altered) were all significantly higher in the high RAD51 group (All p<0.001, Figure 4a). Further, we investigated the amount of immune cell in TME, and several immune cell types (CD4 naive T-cells, CD4+ memory T-cells, T helper type1 cells, T helper type2 cells, Plasma cells, M1 macrophage, and activated dendric cells) were significantly infiltrated in the high RAD51 breast cancer group. Cytolytic Activity score (CYT), which reflects overall immune cell killing, was also significantly increased consistently across all the three cohorts (All p<0.001, Figure4b). Thus, high RAD51 expressing breast cancer is highly immunogenic and has activated cancer immunity.

RAD51 gene expression was associated with triple-negative breast cancer and with lymph node metastasis

To further elucidate the characteristics of high RAD51 breast cancer, we analyzed its association with clinicopathological factors. Consistently among the three cohorts, RAD51 was most strongly expressed in triple negative breast cancer (TNBC) among immunohistochemical subtypes of breast cancer (all p<0.001, Figure5). In contrast, the estrogen receptor (ER)-positive/epidermal growth factor receptor 2 (HER2)-negative subtype had the lowest expression of RAD51. RAD51 expression was higher in advanced stages in TCGA, but this was not validated in the METABRIC cohort. RAD51 expression was significantly increased in the primary tumors of patients with more metastatic lymph nodes in both the METABRIC and GSE96058 cohorts (Both p<0.02), which was not validated in TCGA. On the other hand, the primary breast cancer RAD51 expression did not change with distant metastases. These results suggest that RAD51 is highly expressed in aggressive TNBC and in primary breast cancer with lymph node metastasis.
RAD51 expression is high in tumor that achieved pathological complete response after NAC

Breast cancer with BRCA1 and/or BRCA2 mutation with HRD is known to be sensitive to platinum cytotoxic chemotherapy and PARP inhibitors, and RAD51 expression was reported to be associated with resistance to PARP inhibitors. To this end, the relationship between RAD51 expression and sensitivity to drugs was of interest to investigate. We analyzed the sensitivity to cytotoxic chemotherapies and multiple PARP inhibitors by RAD51 gene expression in breast cancer cell lines from the Depmap portal. In TNBC cell lines, RAD51 expression was positively correlated with sensitivity to docetaxel and epirubicin, but not with cisplatin (Both p<0.05 and r>0.5, Figure6a). However, none of the sensitivity to PARP inhibitors correlated with RAD51 expression (Figure6a). On the other hand, RAD51 expression significantly correlated with sensitivity to niraparib in ER-positive/HER2-negative cell lines (p<0.05 and r=0.9, Figure6a).

As RAD51 was reported to have a role in drug resistance, it was of interest to investigate its association with pathological complete response (pCR) after neoadjuvant chemotherapy (NAC). Interestingly, RAD51 expression consistently decreased after NAC in all 4 cohorts (all p<0.01, Figure6b). A comparison in paired samples before and after NAC showed the same results (Supplementary Figure1). RAD51 expression between groups that did versus those that did not achieve pCR was investigated by immunohistochemical subtype (Figure6c). Although we expected that RAD51 expression to be higher in the residual disease (RD) group, particularly in TNBC, that was the case in only a single cohort (GSE20271 p=0.042, Figure6c). The opposite was found in other cohorts (GSE25066 p=0.001, Figure6c), and most of the cohorts did not show any significant difference in TNBC. In contrast, in the ER+HER2-subtype, RAD51 expression was higher in pCR group across two cohorts (GSE50948 and GSE20271, both p<0.05, Figure6c). These results suggest that RAD51 expression of a bulk tumor does not predict response to NAC.

RAD51 high breast cancer show worse survival consistently in all three cohorts

Given that breast cancers with high expression of RAD51 are more aggressive, it was of interest to investigate whether these characteristics translated into survival disparities. To this end, we compared the survival between high and low RAD51 expression groups. Surprisingly, overall survival (OS) was significantly worse in the high-RAD51 breast cancer group consistently across all three cohorts, and the same was observed in disease-specific survival (DSS) in TCGA and METABRIC. Disease-free survival (DFS) was only significant in METABRIC alone (Figure7). These differences may be because the number of patients and follow-up period are approximately half of that found in the METABRIC compared to TCGA. In short, the expression of RAD51 was associated with a worse prognosis.

Discussion
In this study, we investigated the characteristics of breast cancers with high \textit{RAD51} expression through functional analysis of clinical, immunohistochemical, and transcriptomic data using multiple large breast cancer patient cohorts. First, in line with previous reports, we found that \textit{RAD51} was highly expressed in cancer compared to normal tissues, and strongly correlated with HRD and intratumor heterogeneity. We also showed that the DNA repair gene set, as well as multiple genes related to homologous recombination repair, were significantly associated with high \textit{RAD51} expression. Further, breast cancers with high \textit{RAD51} expression were significantly correlated with histological grade and all five Hallmark cell proliferation-related gene sets, indicating that \textit{RAD51} high tumors are highly proliferative. \textit{RAD51} was also positively correlated with mutation rates. However, \textit{RAD51} expression was not consistently elevated in BRCA mutant tumors compared to wild type. Cancer cell immunogenicity and cancer immune activity were all significantly enhanced in high-\textit{RAD51} tumors across all three cohorts, and infiltration of each immune cell was also observed in all cohorts. Primary tumors of patients with lymph node metastases were associated with high expression of \textit{RAD51} in both TCGA and METABRIC cohorts. There was no strong correlation between \textit{RAD51} expression and drug sensitivity other than Niraparib in the ER-positive/HER2-negative subtype. Contrary to our expectation, \textit{RAD51} expression was lower after NAC compared to the tumor prior to treatment consistently across three independent cohorts. \textit{RAD51} expression was higher in primary tumors that did not achieve pCR after NAC compared to tumors that did in only one among ten independent TNBC NAC cohorts analyzed, whereas this was not validated in any other subtypes in the other cohorts. Finally, overall survival was significantly worse in high \textit{RAD51} breast cancer across all three large cohorts. DSS was also worse in TCGA and METABRIC, and DFS was also worse in METABRIC.

We found that \textit{RAD51} was highly associated with cancer cell proliferation by multiple cohorts, which agrees with Maack et. al. who reported that \textit{RAD51} was more highly expressed in invasive breast cancer with higher grades [15]. \textit{RAD51} was most highly expressed in TNBC, which is known to be the most aggressive subtype of breast cancer. Although not consistent in all cohorts, our study suggested high \textit{RAD51} expression at more advanced stages and in primary tumors with multiple lymph node metastases, which is consistent with a previous report that \textit{RAD51} protein was associated with cancer progression and metastasis of sporadic breast cancer [69]. High-\textit{RAD51} breast cancer had a higher mutational burden and increased neoantigens, and thus, those tumors are more immunogenic. Although there was increased immune cell infiltration in high-\textit{RAD51} breast cancer, none of the immune-related gene sets enriched to \textit{RAD51} high tumor, suggesting anti-cancer immunity was not truly activated. As a result of its strong reflection of cancer aggressors, \textit{RAD51} high expression was significantly associated with poorer prognosis in all the large cohorts analyzed in this study.

\textit{RAD51} was highlighted as a potential marker for predicting treatment response of breast cancer. BRCA-deficient ovarian and breast cancers with HRD show sensitivity to PARP inhibitors and DNA-damaging drugs such as platinum, because these drugs arrest a large number of replication forks and lead to synthetic lethality [70]. Since these processes can be circumvented by \textit{RAD51}, which plays a central role in the repair and restart of replication forks [71, 72], the high expression of \textit{RAD51} is thought to lead to resistance to these drugs [73]. \textit{RAD51} histological expression as identified by fluorescent immunostaining
was found to reflect homologous recombination repair function and was claimed as a predictive marker of pCR after NAC in TNBC [74]. Loss of RAD51 fusion in TNBC correlated with HRD as well as with pCR after platinum-based neoadjuvant chemotherapy [75]. However, RAD51 gene expression in our study showed discrepant results to the previously reported RAD51 assay, which was a functional HRD marker scored by simultaneous expression of both RAD51 and geminin, a cell proliferation marker [74]. Low-RAD51 tumors determined by RAD51 assay were most frequently TNBC, which was opposite to our RAD51 gene expression. Furthermore, high RAD51 expression was positively correlated with HRD, indicating that there may be a dissociation between these functional HRD markers and the gene expression of RAD51. Comparison of drug sensitivity with RAD51 expression suggested that RAD51 expression may be positively correlated with chemotherapy sensitivity in TNBC cell lines, but no resistance to PARP inhibitors was observed. The original RAD51 assay study also showed that RAD51 was barely expressed in the baseline biopsy samples but was upregulated in samples taken immediately after radiation-induced DNA damage [74]. However, RAD51 gene expression was downregulated after NAC in our study comparing pre and post NAC samples. RAD51 was not under-expressed in the group that achieved pCR for NAC, and conversely was highly expressed in the pCR group in some cohorts. It is unclear whether this difference is due to differences between RAD51 gene expression in the RAD51 assay and in bulk tumors, but the function of RAD51 as a marker of drug sensitivity is questionable.

The limitations of this study are as follows. First, there is a patient selection bias in the large cohort included in this analysis, because that patient information was collected more than 10 years ago. Patients receiving newly authorized treatments, such as PARP inhibitors, are not included. Second, the in-vitro cohort was all small, with fewer than 30 cell lines, so a larger number of studies of PARP inhibitors in cell lines may give different results. In addition, we did not perform in-vivo or in-vitro experiments, so the mechanisms by which RAD51 induces cell proliferation and drug resistance will require more detailed testing. In addition, as all our studies have been conducted in retrospective cohorts, prospective studies will need to be designed to investigate the usefulness of RAD51 as a biomarker.

**Conclusion**

RAD51 expression is strongly associated with aggressive biology including proliferation and with poor survival in breast cancer.

Association between RAD51 gene expression and DNA repair. (a) RAD51 expression between normal breast and tumor tissues in TCGA. n; normal breast, t; tumor tissues. (b) The scatter plots between RAD51 gene expression and Intratumoral heterogeneity (left) and Homologues Recombination Deficiency (HRD) score (right) in TCGA. (c) The enrichment plots of DNA repair pathway in gene enrichment analysis (GSEA) comparing high vs low expression of RAD51 divided by a median cut-off in TCGA, METABRIC, and GSE96058 cohorts. The boxplots show the expression of DNA repair-related genes; BRCA1, BRCA2, E2F1, E2F4, E2F7, and CDK12 by high vs low expression of RAD51. FDR less than 0.25 is regarded as significant in GSEA. * = p-value of statistical significance. The r-value indicates Spearman's rank correlation coefficient. All two group comparisons are tested by Wilcoxon signed-rank test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

Figure 2

Association between RAD51 and cancer cell proliferation. (a) The scatter plot of RAD51 gene expression and proliferation score in TCGA. (b) The boxplots of RAD51 gene expression by Nottingham histological grade in TCGA, METABRIC, and GSE96058 cohorts. The scatter plots of MKI67 and RAD51 gene expressions. (c) GSEA of all cell proliferation related gene sets by the high and low expression of RAD51 with a median cut-off in TCGA, METABRIC, and GSE96058 cohort. FDR less than 0.25 is regarded as significant in GSEA. *= p-value of statistical significance. The r-value indicates Spearman's rank correlation coefficient. All multiple group comparisons are tested by Kruskal–Wallis test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

Figure 3
Association of *RAD51* expression with mutation rates and BRCA mutations. **(a)** The boxplots of silent and non-silent mutation rate by the high and low *RAD51* expression with a median cut-off in TCGA. **(b)** The boxplots of *RAD51* gene expression in *BRCA1, BRCA2*, and both wild-type and mutant breast cancer in TCGA and METABRIC. *= p-value of statistical significance. All two group comparisons are tested by Wilcoxon signed-rank test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

**Figure 4**

*RAD51* expression and immune activation and immune cell infiltration. **(a)** The boxplots show immune activity scores from TCGA. **(b)** Immune cell infiltrations by the high and low *RAD51* expression with a median cut-off in TCGA, METABRIC, and GSE96058 cohort. *= p-value of statistical significance. All two group comparisons are tested by Wilcoxon signed-rank test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

**Figure 5**

Relationship between *RAD51* and clinicopathological factors. *RAD51* gene expression by immunohistochemical subtype, stage, lymph node metastasis, and distant metastasis in TCGA, METABRIC, and GSE96058 cohorts. *= p-value of statistical significance. All two group comparisons are tested by Wilcoxon signed-rank test, and multiple groups by Kruskal–Wallis test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

**Figure 6**

Relationship between *RAD51* and drug response in breast cancer. **(a)** The scatter plots of correlation between *RAD51* expression and area under the curve (AUC) of each drug. Docetaxel and cisplatin are from the PRISM primary screen; PARP inhibitors are from the GDSC. **(b)** Boxplots show *RAD51* expression before (light purple boxes) and after (dark purple boxes) NAC. **(c)** All boxplots compare *RAD51* expression...
by immunohistochemical subtype between the two groups, orange for pCR: pathological complete response and light green for RD: residual tumor. *= p-value of statistical significance. The r-value indicates Spearman's rank correlation coefficient. All two group comparisons are tested by Wilcoxon signed-rank test. The error bars in each boxplot show the 95% confidence interval. The line in the box shows the median, and top and bottom show the 25th and 75th percentiles respectively.

**Figure 7**

**Survival analyses by RAD51 expression.** Kaplan-Meier survival curves of the DFS, DSS and, OS by RAD51 high vs. low expressions with a median cut-off in TCGA, METABRIC, and OS of the GSE96058 cohort. High groups are indicated by red lines, low groups by blue lines. *= p-value of statistical significance. Log-rank test was used to test the significance of the survival analysis. The r-value indicates Spearman's rank correlation coefficient.
