Interaction of neuropsychiatric symptoms with APOE ε4 and conversion to dementia in MCI patients in a Memory Clinic

Valero Sergi1,2*, Marquié Marta1,2, Rojas De Itziar2, Espinosa Ana1,2, Moreno-Grau Sonia1, Orellana Adelina1,2, Montreuil Laura1, Hernández Isabel1,2, Mauleón Ana1, Rosende-Roca Maitée1, Alegret Montse1,2, Pérez-Cordón Alba1, Ortega Gemma1,2, Roberto Natalia1, Sanabria Angela1,2, Abdelnour Carla1, Gil Silvia1, Tartari Juan Pablo1, Vargas Liliana1, Esteban-De Antonio Ester2, Benaque Alba1, Tàrraga Lluís1,2, Boada Mercè1,2 & Ruiz Agustín1,2

To date, very few studies have been focused on the impact of the convergence of neuropsychiatric symptoms (NPS) and APOE ε4 on the conversion to dementia in patients with Mild Cognitive Impairment (MCI), and none has been based in a clinical setting. The objective of the study is to determine the predictive value of additive and multiplicative interactions of NPS and APOE ε4 status on the prediction of incident dementia among MCI patients monitored in a Memory Clinic. 1512 patients (aged 60 and older) with prevalent MCI were followed for a mean of 2 years. Neuropsychiatric symptoms were assessed at baseline using the Neuropsychiatric Inventory Questionnaire. Cox proportional hazards models were calculated. Additive interactions for depression, apathy, anxiety, agitation, appetite, or irritability and a positive ε4 carrier status were obtained, significantly increasing the hazard ratios of incident dementia (HR range 1.3–2.03). Synergistic interactions between NPS and APOE ε4 are identified among MCI patients when predicting incident dementia. The combination of the behavioral status and the genetic trait could be considered a useful strategy to identify the most vulnerable MCI patients to dementia conversion in a Memory Clinic.

Mild Cognitive Impairment (MCI) is a relevant syndromic entity characterized by early stages of cognitive decline with preserved autonomy and it is frequently associated with neurodegenerative diseases, Alzheimer's disease (AD) being the most prevalent one. As MCI is considered an intermediated diagnosis between normal cognition and dementia, much effort has been dedicated to the identification of those individuals with MCI with a higher vulnerability of conversion to dementia. The study of the simultaneous effect of neuropsychiatric symptoms and genes is increasing its interest in recent years. Considering that a susceptibility condition can be better explained by the confluence of a behavioral status and the effect of one or more genes, the main idea is to highlight the relevance of gene–behavioral interactions. To date, only two studies have looked into the interaction between NPS and APOE ε4 when determining an increased risk of the hazard of an eventual case of dementia. These studies have shown significant interactions between behavioral disturbances and APOE ε4 in predicting of incident dementia in cognitively healthy individuals or MCI patients extracted from population-based cohorts. However, nothing is known about the combined contribution of these two risk factors on the conversion to dementia in MCI patients diagnosed and followed in a Memory Clinic. The objective of the present study is to determine the effect of interaction of NPS and APOE ε4 on conversion to dementia in a large sample of MCI patients, controlling for several relevant clinical factors.

Methods

Participants. Patients were recruited and assessed at the Memory Clinic from Fundació ACE, Institut Catàlal de Neurociències Aplicades (Barcelona, Spain), from 2005 to 2018. Informed consent was obtained from all participants. The referral center ethics committee (Hospital Clinic i Provincial of Barcelona) approved the patient recruitment and collection protocols. All diagnoses were assigned at a daily consensus conference among neurologists, neuropsychologists, and social workers. At the time of enrollment patients fulfilled Petersen's MCI diagnostic criteria1, including subjective memory complaints, normal general cognition, preserved performance of daily living activities, absence of dementia, and a measurable impairment in one or more cognitive functions. Patients also had the following characteristics: a Clinical Dementia Rating Scale (CDR) of 0.5, age older than 60 years of age, functionally literate, and without severe auditory or visual abnormalities including glaucoma and cataracts. Participants received standardized neurobehavioral exams, including neurological examination, neuropsychological testing, and social work evaluations. Information about vascular risk factors (including hypertension, hypercholesterolemia, diabetes mellitus, history of stroke, heart disease) and family history of dementia was provided by the patients or their caregivers. All subjects underwent the neuropsychological battery of Fundació ACE (NBACE) for diagnostic purposes. A total of 4173 MCI patients had one or more clinical follow-up visits at the Memory Clinic. Among these patients, 2030 had available DNA sample and, among them, 1512 had a basal assessment of NPS. Participants finally included in the study (n = 1512), in comparison with those excluded (n = 2661), were statistically homogenous in age and gender. They had, however, lower MMSE (25.86 vs 26.1; p = 0.002) and more years of education (6.88 vs 6.37; p < 0.001). Both differences showed an effect size (d) < 0.13.

Neuropsychological assessment. All MCI patients completed the neuropsychological battery of Fundació ACE (NBACE)11. This diagnostic procedure assesses eight cognitive domains, as follows: (1) Orientation—temporal, spatial, and personal orientation; (2) Attention and working memory—digit spans (forwards and backwards) subtests from the Wechsler adult intelligence scale—third edition (WAIS-III); (3) Processing speed and Executive function—the automatic inhibition subtest from the Syndrome Kurz Test (SKT); phonetic verbal fluency (words beginning with ‘P’ in 1 min); semantic verbal fluency (‘animals’ in 1 min); the similarities subtest from WAIS-III (abbreviated to the first 10 items); (4) Language—repetition (two words and two sentences); verbal comprehension (to correctly execute two simple, two semi-complex, and two complex commands extracted from the Alzheimer’s disease assessment scale (ADAS) and the Barcelona test battery); an abbreviated 15-item Boston naming test; (5) Verbal Learning and Memory—word list learning test from the Wechsler memory scale—third edition (WMS-III) (without using the interference list); (6) Praxis—block design subtests from WAIS-III (abbreviated so that items 6 to 9 were scored only for accuracy (1 point) without a time bonus); imitation praxis (four items); ideomotor praxis (four items); (7) Visual gnosis—the Poppelreuter test, Luria’s clock test, and the 15-objects test; and (8) Global cognition—the Spanish version of the clock test.

APOE genotyping. Genomic DNA was extracted from peripheral blood using the commercially kit available Chemagic system (Perkin Elmer). The APOE genotypes were determined with the use of fluorogenic allele-specific oligonucleotide probes (TaqMan assay; Life Technologies, Spain) for rs7412 (Test ID: C_904973_10) and rs429358 (Test ID: C_3084793_20). For the TaqMan assays, PCR and real-time fluorescence measurements were carried out in QuantStudio3 real-time PCR system (Thermo Fisher Scientific, Spain) using the TaqMan Universal Master Mix (ref: 4364341, Life Technologies, Spain) methodology according to manufacturer’s instructions. Polymerase chain reaction was performed as follows: first, a pre-read step for 30 s at 60 °C, a denaturation for 10 min at 95 °C, followed by 40 cycles at 95 °C for 15 s and 60 °C for 1 min, and a post-read stage for 30 s at 60 °C. The genotype was determined using the Genotyping App for Thermo Fisher Cloud by clustering analysis. The laboratory technicians were blinded to other study variables.

MCI converter and non-converter criteria. Subjects who converted to dementia (including AD13 vascular dementia14, mixed dementia (AD with cerebrovascular disease), frontotemporal dementia15,16, or dementia with Lewy bodies17) over the study period, were classified as MCI converters. All of these subjects had a CDR of 1. In contrast, those subjects who remained stable during follow-ups were classified as MCI non-converters.

Memory impairment and etiology patterns. MCI subjects were classified as amnestic or non-amnestic, according to Petersen’s criteria1. Potential causative factors were also clinically examined to attribute etiology. As multiple causative factors can be recognized in a patient, only the primary was assigned according to its salience. Four MCI patterns were finally generated: degenerative, vascular, psychiatric, and others18-21. Patients were
classified under the Other condition when neither of the aforementioned three causal conditions was identified as preeminent.

**Personal and family history.** Family medical history of neurological conditions, including dementia, Huntington’s disease, Parkinson’s disease, psychiatric conditions or Down syndrome were recorded for the MCI participants and encoded as 1 or 0 (present/absent), according to information reported by patients and caregivers. The exploration of these conditions included current or past conditions of parents, grandparents, siblings and children. In order to have a simple approach to all these variables as an adjusting factor, they were combined using Component Analysis. The five conditions were included in the factorial analysis and a solution of one-factor was forced. The resulting factorial loadings were used here as a proxy of the Family medical history of neurological conditions. This new standardized variable was identified in this study as FamMedHist_comp. Comorbidities of MCI subjects were also explored. Hypertension, dyslipidemia, diabetes, cardiopathy, stroke, traumatic brain injury, epilepsy, depression, COPD, kidney disease, thyroid disease, osteoarthritis, current or past comorbidities of patients, were also encoded as present or absent (1/0). These 12 variables were processed by a Component Analysis, in the same way as the FamMedHist_comp variable. Factorial loadings here obtained were called MedComorb_comp.

**Antidepressant and anxiolytic medication.** The use of antidepressant and anxiolytic medications was registered. Every variable was coded as 1 if the medication prescription was observed at least once during the follow-up or 0 when no medication was prescribed.

**Analytical procedure.** To explore the association between NPS and conversion to dementia, a Chi-Square test was conducted. Hazard ratios (HRs) and 95% confidence intervals (95% CIs) were used to assess the association between the independent variables, NPS and APOE genotype, and the outcome of conversion to dementia using Cox proportional hazard models. Interaction effects between NPS and the APOE ε4 genotype were the main targets of the analyses. The corresponding and necessary main effects of interactions (the neuropsychiatric symptom and APOE effects alone) were also included in the model. Additive and multiplicative interactions were explored. Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) recommendations for the analysis of interactions were followed; that is, we reported different effects of the two risk factors and their joint effect using one reference category, thus providing enough information to calculate interaction on an additive and multiplicative scale22. Interactions and main effects were coded following Andersson23. Cox models were dually calculated, adjusted or not by age, gender, years of education, baseline MMSE, memory pattern (amnestic vs. nonamnestic), FamMedHist_comp, MedComorb_comp, etiology (degenerative, vascular, psychiatric, and others) and prescription of antidepressant and anxiolytic medication. Etiology, as a categorical variable, was recoded by obtaining dummy variables, considering degenerative status as the reference category. In the description of data, and to provide more accurate estimations, especially for NPS with small samples, confidence intervals for means and proportions were calculated by bootstrapping (k = 500). Statistical testing was done at a conventional two-tailed at a level of p < 0.05. Statistical analyses were performed using STATA 15 (Stata Corporation, College Station, Texas).

**Results**

At baseline, the prevalence of NPS in the MCI cohort ranged from 55% for depression and anxiety to less than 0.5% for elation/euphoria or motor disturbances. Heterozygous or homozygous APOE ε4 genotypes were observed in 31% of the total sample. The follow-up had a mean of 2.03 years (DE = 1.68; median = 1.38; percentile 25 = 0.98; percentile 75 = 2.42). 67.9% of the total sample were amnestic MCI. The suspected etiology for the MCI was done at a conventional two-tailed at a level of p < 0.05. Statistical analyses were performed using STATA 15 (Stata Corporation, College Station, Texas).

When exploring the distribution of NPS between APOE ε4 carriers and noncarriers (Table 2), only anxiety symptoms presented a significant association with this allele (p = 0.002). In particular, results showed that among APOE ε4 carriers, the proportion of anxiety was lower than among noncarriers. For the rest of NPS, the proportion of APOE ε4 carriers was statistically homogenous.

Clinical differences between converters and non-converters are presented in Table 3. Older age, female sex, fewer years of education, APOE ε4 carrier status, lower baseline MMSE scores were more common among converters (p < 0.008 for all variables). Amnestic MCI patients were statistically more prevalent among converters than non-converters (p < 0.001). Concerning etiology, the degenerative condition appeared heterogeneously distributed between converters and non-converters. Close to 38% of converters were characterized by this condition, while within non-converters this percentage was 22.9%. Vascular and psychiatric etiological conditions were also comparable between both groups. The “Other” condition was more prevalent among non-converters.

Regarding NPS, the presence of baseline apathy, agitation/aggression, night behaviors, appetite/eating, and disinhibition showed a significant effect on conversion to dementia. Night behaviors showed an inverse profile (higher prevalence of this NPS in the non-converter group). Depression and anxiety were the most prevalent symptoms in the total sample, but along with irritability, delusions, and hallucinations showed a nonsignificant differential effect on conversion to dementia.

Table 4 shows Cox regression analyses for NPI, APOE ε4, and its interaction on survival time to conversion to dementia. When non-adjusted results were explored, additive interaction of APOE ε4 with depression, apathy, anxiety, appetite, and night behaviors emerged as significant. In a multiplicative scale, none of the interactions

Table 2. Neuropsychiatric symptoms in APOE4 carriers and noncarriers. aFisher exact test.

showed a significant effect. Under adjusting effect, all significant results previously reported for additive interactions, except for night behaviors, emerged again as significant. Multiplicative interaction for apathy was the only one with a significant result but showing an inverse effect (HR = 0.74). Appetite and agitation presented the highest incremental risk of conversion to dementia (> 85%) in the additive interactions with APOE ε4 (Fig. 1).
When considering significant additive interactions under the adjusted model, those associated with agitation/aggression and appetite/eating showed a specific profile. In contrast with depression/dysphoria, apathy or anxiety, interaction effects for agitation/aggression presented the highest risk between all NPS and the most discriminant effects in comparison to the corresponding behavioral and genetic main effects. Irritability had a unique effect within this set of results: its additive interaction was (statistically) lower than the sum of the corresponding main effects.

Within the MCI converters group, it was observed that 74% participants converted to AD, 12% to vascular dementia and 4.3% to Frontotemporal dementia, while the rest converted to different etiologies of dementia. When differentiating between AD vs other forms of dementia, a logistic regression analysis was performed, including the ten relevant neuropsychiatric symptoms as predictors, and adjusted by the same variables used in the survival analysis. Apathy emerged as the only significant symptom when detecting conversion to other kind of dementia different than AD, although with a weak effect (Wald = 4.20, p = 0.041, 95%CI: 1.01–1.96).

Discussion

Although relevant differences can be observed among studies, behavioral disturbances have been considered a prevalent condition among MCI patients and have been associated with a significant and increased risk of incident dementia, particularly AD. At the same time, these symptoms have been considered some of the earliest clinical manifestations of prodromal AD. The study results have to be highlighted for two reasons. First, this is the first one exploring the connection between behavioral and genetic risk factors for conversion to dementia in MCI patients in a Memory Clinic. Second, our results evidence the relevance of exploring the incremental predictive value of interaction between risk factors beyond standard approaches based on the analyses of only risk factors’ main effects. Our data demonstrate a synergistic effect of depression, apathy, anxiety, agitation, appetite and irritability, and a positive ε4 carrier status. These significant results are particularly relevant because there is no previous evidence, according to meta-analytical approaches, that the APOE ε4 genotype and behavioral symptoms are associated in MCI patients, except in the case of anxiety, where a differential distribution of the symptom seems to be associated to the APOE ε4 condition. Interestingly, all these observations are concordant with our study’s conclusions. The most relevant consideration, however, is that a higher prevalence of APOE ε4 carriers is not expected when a NPS is present, at least for the majority of symptoms. Behavioral disturbances and APOE ε4 are independent factors that, when they converge in MCI patients, manifest themselves most severely predicting conversion to dementia. Interestingly, nearly all NPS involved in additive interactions in the present study had been previously identified as the most remarkable ones when differentiating between cognitively normal adults and AD patients.

Our results are convergent with those observed in a population-based study by Burke et al. where, in a sample of more than 11,000 cognitively intact participants, delusions, hallucinations, agitation, depression, anxiety, elation apathy, disinhibition, irritability, motor disturbances, appetite, and sleep disturbances appeared to have additive interactions with APOE ε4 as risk factors for dementia conversion. In a study by Pink et al., which examined 332 MCI patients from a population-based sample, additive interactions with APOE ε4 were also observed for apathy and depression. Hence, we propose that previous observations are generalizable to the MCI phenotype and might be of interest as predictors of the conversion to dementia in this population.

A multiplicative interaction with a significant outcome is an exceptional result. Only in Burke et al. a remarkable interaction in this scale was observed for delusions and motor disturbances. In our study, apathy was the only behavioral condition with a significant result in a multiplicative interaction with APOE ε4, but its effect has to be interpreted in terms of a reduction in the risk rate. Exceptional or poor results associated with multiplicative interactions in the context of Cox regression models, however, should not be surprising: it means that

Table 4. APOE ε4 and NPS main effects and their interaction in additive and multiplicative scale.

aNonadjusted. bAdjusted by sex, age, years of education, MMSE, FamMedHist_comp, MedComorb_comp, amnestic and etiology MCI subtype, and antidepressant/anxiolytic medication.
that AD with psychosis could be considered a specific phenotype with a genetic basis. However, in cognitively impaired subjects, and as it was previously reported, associations between NPS and APOE ε4 seem to be highly consistent and, given the lack of other evidence, the results could be interpreted in terms of an intrinsic association between the combined effect of both risk factors and conversion to dementia in MCI patients.

When focusing on the detail of the hazard ratio sizes observed in the additive interactions between NPS and APOE ε4, it is observed that synergistic effects have an incremental risk of dementia conversion ranging from 30% to more than 100% compared to nonaffected MCI peers. The average risk is close to 60%. This estimation is particularly relevant when observing that the incremental mean risk of conversion to dementia associated with APOE ε4 and NPS' main effects are 44% and 14%, respectively. Agitation/aggression and appetite appeared as the most discriminant conditions for dementia conversion, not for the symptoms themselves (appetite has a low predictive value compared with other NPS), but when presented simultaneously with the genetic trait. This specific risk profile, where the additive interaction emerges as a high predictive condition in contrast to its main effects, has to be highlighted. MCI patients affected by agitation/aggression or appetite/eating symptoms are not so frequent, but when they additionally present an APOE ε4 carrier status become the patients with the poorest prognosis, that is, have the highest risk of progression to dementia.

Knowing the biological mechanisms that underlie is, of course, a relevant scientific target by itself but is also a key objective when trying to identify better treatments. Knowing these mechanisms may help us define new neurochemical mechanisms and better understand how pharmacologic and non-pharmacologic treatments help affected people. Unfortunately, the current understanding of neuropsychiatric symptoms' neurobiology is limited, especially when considering preclinical and prodromal stages of AD. Scientific literature has considered that different patterns of NPS are associated with distinct MCI subtypes, and differences in conversion rates between NPS could be partially consequence of these clinical subtypes. For example, more severe agitation/hyperactivity symptoms over time are observed in MCI patients with anamnestic profile subtype. Other explanations have been formulated connecting the occurrence of particular NPS with specific brain networks or circuits in the brain, or proposing that brain changes, presented in preclinical stages, could be explaining the differential clinical progression of patients, including NPS manifestations. When focusing on genetic research, one central idea is to suggest that genes identified as risk factors of developing AD could also be risk factors for developing particular NPS. Some studies have shown consistent associations between APOE ε4 and psychosis in AD. Heritability of psychotic symptoms in AD is estimated to be up to 61%, and, in fact, it has been postulated that AD with psychosis could be considered a specific phenotype with a genetic basis. However, in cognitively impaired subjects, and as it was previously reported, associations between NPS and APOE ε4 are unclear. Beyond APOE, although it has been demonstrated that that sortilin-related receptor 1 gene (SORL1) and the
ATP-binding cassette, subfamily A, member 7 gene (ABCA7) are associated with AD, the connection of these high-risk genes with NPS occurrence has to be also considered inconclusive. NPS in AD and its preclinical and prodromal conditions have a heterogeneous presentation. They are changeable and do not constitute a unitary or homogeneous status. This natural manifestation of the symptoms could be explaining, at least partially, the difficulties in finding consistent results.

The limitations of the study have to be stated as well. The first one is the limited extension of follow-ups. Data up to only two years after the initial clinical evaluation have been explored. The exploration of MCI as a prodromal stage of dementia should be studied with longer follow-ups to determine the consistency of estimated synergistic hazard ratios. A second consideration is associated with the universe of NPS that were analyzed. Elation/euphoria and motor disturbances were excluded from analyses because of their low prevalence, despite the analysis of a cohort of more than 1500 patients. The solution to this selective loss of information may have a problematic approach in the context of a Memory Clinic. First, these symptoms are rare among MCI patients. Large samples of patients are needed to consistently approach an interaction analysis, something that is usually difficult in clinical settings. Second, even in the context of a Memory Clinic that works under an integrated care paradigm, patients with these particular behavioral conditions are sometimes referred to other more specialized healthcare resources, losing the opportunity of a conversion estimation. Finally, it is well known that APOE ε4 has been identified as a risk factor for AD, while in this study, the conversion rates are calculated for all forms of dementia. Under our consideration, this potential loss of precision when using APOE status in an interaction with a NPS has a relative relevance. First because, as reported above, in the converted subgroup of MCI, the majority of cases are AD (three out of 4 cases) and, second, because the main idea was to identify critical variables when predicting a conversion, any kind of conversion, in the context of an applied setting.

Conclusions
This study identifies, in a Memory Clinic setting, additive interactions between depression, apathy, anxiety, agitation, appetite, and irritability and APOE ε4 as predictors of conversion to dementia in MCI patients. The neuropsychiatric condition and the genetic trait are essentially independent factors between them, but when they converge in a patient, the combination emerges as the most discriminant condition for conversion to dementia, beyond the impact of most of the single risk factors. Results of this study represent a step further in the identification of the most exposed MCI patients to dementia conversion and, for the first time, in an applied setting. To date, the APOE status cannot be treated, but the neuropsychiatric condition of MCI patients could be targeted by direct or indirect interventions, pharmacological or not. Professionals working in clinical settings can take advantage of these results, not only trying to mitigate the intensity and frequency of current behavioral disturbances but also improving the quality of life of affected people.
