**ABSTRACT** *Capsicum chinense* is one of the five domesticated pepper species belonging to the Solanaceae family. *Capsicum* sp. have been used as model systems in comparative and evolutionary genomics because of their superior availability of chloroplast genome in the solanaceae family. Similarly, molecular markers derived from the complete chloroplast genome can provide effective tools for species identification and phylogenetic resolution. So far, however, only partial taxonomic and phylogenetic analyses have been carried out for the genus. Thus, the complete chloroplast genome sequence of a cultivated pepper (*C. chinense*) has been reported here. The total length of the chloroplast genome is 156,936 bp, with 37.7% overall GC content. A pair of inverted repeats (IRs) of 25,847 bp was separated by a small single copy (SSC) region of 17,912 bp and a large single copy (LSC) region of 87,330 bp. The chloroplast genome harbors 113 known genes, including 79 protein-coding genes, four ribosomal RNA genes, and 30 transfer RNA (tRNA) genes. In all, 21 of these genes are duplicated in the inverted repeat regions, 15 genes and six tRNA genes contain a single intron, while two genes have two introns. Analysis revealed 117 simple sequence repeat (SSR) loci, which are mostly located in the intergenic regions. The complete chloroplast genome reported here enriches our knowledge of the genetic complement of *C. chinense*, and contributes to our understanding of the genetic relationships within the genus *Capsicum*.

**Keywords** *Capsicum chinense*, Chloroplast, DNA sequencing, Hot pepper

**INTRODUCTION**

*Capsicum* L. (Solanaceae) is one of the most economically important vegetable crops with versatile applications as a food and source of spice, as well as for ornamental and pharmaceutical purposes (Qin *et al*. 2014). The tropical regions of South America are believed to be the origin of peppers which are now grown worldwide (Greenleaf 1986). Today, the *Capsicum* genus consists of about 25 wild species and five cultivated species which include *C. annuum* L., *C. baccatum* L. var. pendulum (Willd.) Eshbaugh., *C. chinense* Jacq., *C. frutescens* L., and *C. pubescens* Ruiz & Pav. (Kumar *et al*. 2006). Species identification in *Capsicum* is traditionally based on phenotypic characteristics and hybridization studies (Heiser and Smith 1953; Pickersgill 1988; Hunziker 1998; Onus and Pickersgill 2004). However, species identification based on morphological characteristics is often difficult, since most of these features are also influenced by environmental factors. In the last few decades, genotypic molecular markers have been identified, and are gaining increasing importance in resolving phylogenetic relationships. *Capsicum chinense* is well known for its distinctive pungency causing severe heat sensation and has been recorded as the hottest pepper in the world (Bosland and Baral 2007). Characterization of genebank accessions is an
important step for germplasm conservation, maintenance, and breeding studies. Several methodologies have been widely applied to analyze genetic variability in *Capsicum* species diversity studies. These include using phenotypic markers such as morphological and agronomic descriptors and genotypic markers such as restriction fragment length polymorphism (RFLP) (Lefebvre et al. 1993), amplified fragment length polymorphism (AFLP) (Aktas et al. 2009), random amplified polymorphic DNA (RAPD) (Adetula 2006; Moses and Umaharan 2012), microsatellite or simple sequence repeat (SSR) (Portis et al. 2007; Stagel et al. 2009; Pacheco-Olvera et al. 2012), random amplified microsatellite polymorphism (RAMPO) (Rai et al. 2013) and direct amplification of minisatellite DNA (DAMD-PCR) (Ince et al. 2009).

Recently, whole genome sequencing strategies have been used to explore many plant species at the molecular level in rapid and cost-effective ways (Cao et al. 2011). Fragments of DNA from the chloroplast (cp) genome have been widely used for phylogenetic reconstruction and species-level identification because of their relatively stable genomic structure and higher evolutionary rate relative to mitochondrial genomes (Dong et al. 2012). The complete cp genome sequences of cultivated peppers have been reported (Jo et al. 2011; Zeng et al. 2016; Shim et al. 2016; Park et al. 2016; Kim et al. 2016). The main objective of this study was to sequence the complete cp genome and examine the genetic architecture of *C. chinense* with a view to resolving its internal relationships.

**MATERIALS AND METHODS**

**Sampling and DNA extraction**

The cultivated pepper (Accession No: IT247196) seeds were collected from the National Agrobiodiversity Center, Rural Development Administration, Republic of Korea. Seeds were germinated and grown in a greenhouse, fresh leaves were collected from 40-day-old seedlings and DNA was extracted to construct cp DNA library.

**Chloroplast genome sequencing and assembly**

An Illumina paired-end cp DNA library (average insert size of 500 bp) was constructed using the Illumina TruSeq library preparation kit following the manufacturer’s instructions. The library was sequenced with 2 × 300 bp on the MiSeq instrument at LabGenomics (http://www.labgenomics.co.kr/). Assembly of complete cp genome sequences was performed by de novo assembly of the low coverage whole genome sequence (WGS), via a bioinformatics pipeline (http://www.phyzen.com). Briefly, prior to de novo cp genome assembly, low quality sequences (quality score < 20; Q20) were filtered out, and the remaining high quality reads were assembled using the CLC GenomeAssembler (version beta 4.6, CLC Inc. Aarhus, Denmark) with a 200 - 600-bp overlap size. Cp contigs were selected from the initial assembly by performing a BLAST (ver. 2.2.31) search against known cp sequences. The selected contigs were oriented to construct the complete cp genome structure. Ambiguous nucleotides or gaps were corrected manually to build the complete cp genome.

**Chloroplast genome annotation**

The web-based program Dual OrganellarGenoMe Annotator (DOGMA, http://dogma.ccbb.utexas.edu/) was used to annotate the assembled genome using default parameters to predict protein coding, transfer RNA (tRNA) genes and ribosomal RNA (rRNA) genes. Subsequently, BLASTN (ver. 2.2.31) was used to further identify intron-containing gene positions by searching a published cp genome sequence (GenBank accession NC_018552). A cp gene map was constructed using the OrganellarGenomeDRAW software (OGDRAW, http://ogdraw.mimp-golm.mpg.de).

**Discovery of SSRs and SNPs**

MicroSatellite identification tool (MISA) software (http://pgrc.ipk-gatersleben.de/misa/) was used to find the SSR markers present in the cp genome. This software allows the localization and identification of both perfect and compound microsatellites with 1 to 6 nucleotides in the basic repeat unit. To be considered a microsatellite using this approach, a sequence must be present for a minimum of 10 repeat units for mononucleotide motifs, six repeat units for dinucleotide motifs and five repeat units for all motifs of larger size. MISA has been used for SSR identification in
many species including *Eucalyptus* (Ceresini et al. 2005) and barley (Thiel et al. 2003). To identify SNP and InDel variants in the cp genome, we used msaTovcf program locally modified with an in-house script (Page et al. 2016).

**Comparative phylogeny**

A new multiple sequence alignment was performed by adding 13 species belonging to the Solanaceae family. The resulting alignment was imported in MEGA 6.0 for inferring maximum parsimony (MP) analysis, setting 1000 bootstrap replications, Tree-Bisection-Regrafting (TBR) algorithm and 10 random addition replicates. All positions containing gaps and missing data were eliminated. Phylogenetic tree was generated by a maximum likelihood (ML) analysis using MEGA 6.0 with 1000 bootstrap replicates (Tamura et al. 2013).

---

**Fig. 1.** Complete chloroplast genome map of the cultivated pepper (*Capsicum chinense*). Genes drawn inside the circle are transcribed clockwise, while those outside are counterclockwise and marked with two arrows. Differential functional gene groups are color-coded. The GC content variation is shown in the middle circle.
RESULTS

Chloroplast genome assembly

Illumina sequencing generated 10,056,140 paired-end reads, with an average fragment length of 280 bp, which were then analyzed to reveal 3,017,719,480 bp of sequence. After removal of low-quality reads (Q20), the remaining high quality reads were mapped to the reference cp genome of *C. annuum* L. (GenBank accession NC_018552). As nucleic DNA was not excluded during DNA extraction, a total of 128,000 cleaned reads were mapped with an average coverage of 173× on the cp genome. The cp reads extracted from the Illumina dataset were assembled into a total of four contigs. A complete cp genome was constituted without gaps, from overlaps between contigs (Fig. 1). The whole genome sequencing approach successfully allowed micro-reads to be assembled correctly using a reference-guided method. The fully annotated cp genome sequence of the cultivated pepper *C. chinense* has been deposited in the GenBank database under accession number KX913217.

Features of the chloroplast genome

The complete cp genome of *C. chinense* is 156,936 bp in length. It has the typical angiosperm plastome structure, including a pair of inverted repeats (IRA and IRB) of 25,847 bp that separate the large single-copy (LSC) region of 87,330 bp from the small single-copy (SSC) region of 17,912 bp. The overall GC content of the cp genome is 37.7%, while the LSC and SSC are 35.8 and 32.0%, respectively. The cp genome contains 79 protein coding genes, 30 tRNA genes and four rRNA genes, totaling 113 unique genes (Table 1). Of these, 21 genes are duplicated in the inverted repeat regions, 15 genes and six tRNA genes contain one intron, while two genes (*ycf3* and *rps12*) have two introns.

| Features | Chloroplast |
|----------|-------------|
| Genome size (bp) | 156,936 |
| GC content (%) | 37.7 |
| Total number of genes | 113 |
| Protein coding genes | 79 |
| No. of rRNA genes | 4 |
| No. of tRNA genes | 30 |
| No. of gene duplications in IR regions | 21 |
| Total introns | 17 |
| Single intron (gene) | 15 |
| Double intron (gene) | 2 |
| Single intron (tRNA) | 6 |

Discovery of SSRs and SNPs

Cp SSRs (cpSSRs) analyzed with MISA Perl script revealed a total of 117 potential SSRs motifs which are located primarily in the intergenic region (Supplementary Table S1). The majority of the cpSSRs in this cp genome are tri-nucleotides (58.11%) and di-nucleotides (36.75%). Only six tetra-nucleotides (5.12%) were present in the *C. chinense* cp genome. SNP and InDel variants extracted from a multi-FASTA alignment with reference cp genome sequence of *C. annuum* (JX270811) revealed a total of 174 mutations (82 SNPs and 92 InDels) and 69 of these variants involving more than one nucleotide (Supplementary Tables S2 and S3). Among the detected variants, 35 SNPs and 7 InDels were observed in the genic region of the cp genome.

Phylogenetic analysis

The phylogenetic relationship between *C. chinense* and other Solanaceae family members was determined by collecting 13 published cp genome sequences from GenBank of the NCBI database (Fig. 2). Resulting alignment and ML phylogenetic tree using MEGA 6.0 strongly indicated that the *C. chinense* was 129-bp larger than the reported *C. chinense* cp genome (KU041709.1) and much closer to *C. annuum* var. *glabriusculum*, a wild progenitor of *C. annuum*, than other *Capsicum* species. All the nodes in the phylogenetic tree received high bootstrap (100%).

DISCUSSION

Cp sequences have been used to identify different plant species with DNA barcoding methods (Walsh and Hoot 2001; Martine *et al.* 2006). Furthermore, massively parallel
sequencing technologies have efficiently increased the phylogenetic resolution of land plants at low taxonomic levels (Parks et al. 2009). In recent years, cp DNA has been considered a promising approach for the study of plant evolution, as many published chloroplast genome sequences are available in the NCBI database. In this study, Illumina re-sequencing and assembly of the C. chinense cp genome has an indicated length of 156,936 bp which is
129-bp larger than the reported *C. chinense* cp genome (156,807 bp). Total GC contents were 37.7%, which is consistent with reported cp genomes of *C. chinense* and other cultivated peppers (Jo *et al*. 2011; Park *et al*. 2016).

Cp structural rearrangements and gene loss/gain events occur frequently in some angiosperms. The organization and gene architecture of the *C. chinense* cp genome exhibited similar characteristics, with a total of 113 genes as reported in the previous study. However, in the present study only 21 genes were duplicated in IR regions. As shown in Fig. 1 and Table 2, the genome organization appeared to be more conserved among unique genes, as discovered previously in the *Capsicum* species (Park *et al*. 2016; Zeng *et al*. 2016). The conserved gene sequences in the cp genome indicated that maintenance of gene clusters might be essential for normal gene expression. The sequence data generated using the Illumina platform covered a greater depth (173×) than has previously been reported, thus, the cp assembly described here with its new insights supports the suggestion of a previous report recommending the significance of greater genome coverage (Wu *et al*. 2014).

Microsatellite SSRs are widely used as markers in phylogenetic investigations because of their polymorphic nature within the species (Xue *et al*. 2012). A total of 117 potential cpSSRs were identified in the *C. chinense* cp genome with most of them being intergenic. These results are in agreement with trends of SSR density observed in small genomes (Morgante *et al*. 2002). Similarly, pairwise comparison of the *C. chinense* cp genome with the reference cp sequence revealed a total of 174 mutations (82 SNPs and 92 InDels) with 69 of these variants involving more than one nucleotide, indicating that they can be used as molecular markers to study the genetic diversity and genetic structure of the *Capsicum* species.

A new multiple sequence alignment was performed by downloading 13 Solanaceae species from NCBI. Resulting alignment and phylogenetic analysis using MEGA 6.0 indicated *C. chinense* was 129-bp larger than the reported *C. chinense* cp genome (KU041709.1). As shown in Fig. 2, the constructed ML tree indicated three major clades, Capsiceae, Solaneae, and Nicotianaeae, with very high overall bootstrap values and is in agreement with the results of an earlier study (Park *et al*. 2016).

In conclusion, Illumina sequencing followed by *de novo* assembly and extensively annotated cp genome of the most important vegetable crop in the Solanaceae family (*Capsicum*) were reported. The cp genome is well-conserved in terms of size, gene arrangement, and coding sequences, within major subgroups of *Capsicum* as reported. We also performed comparative analyses with cp genomes sequenced in other Solanaceae species. These analyses revealed that cpSSR sequences were particularly frequent in the *C. chinense* cp genome which is similar to other small plastomes of land plants. Moreover, the ML tree determined the evolutionary position of the pepper in the Solanaceae family. This new genomic dataset will enable further exploration of the genetic diversity of *C. chinense* in the genus *Capsicum*.

**ACKNOWLEDGEMENTS**

This study was carried out with the support of the “Research Program for Agricultural Science & Technology Development (Project No. PJ010898)” and was supported by the 2016 Postdoctoral Fellowship Program of the National Institute of Agricultural Sciences, Rural Development Administration, Republic of Korea.
