ABSTRACT

We examine the small-scale dynamics of black hole accretion disks in which radiation pressure exceeds gas pressure. Local patches of disk are modeled by numerically integrating the equations of radiation MHD in the flux-limited diffusion approximation. The shearing-box approximation is used, and the vertical component of gravity is neglected. Magnetorotational instability (MRI) leads to turbulence in which accretion stresses are due primarily to magnetic torques. When radiation is locked to gas over the length and timescales of fluctuations in the turbulence, the accretion stress, density contrast, and dissipation differ little from those in the corresponding calculations, with radiation replaced by extra gas pressure. However, when radiation diffuses each orbit a distance that is comparable to the rms vertical wavelength of the MRI, radiation pressure is less effective in resisting squeezing. Large density fluctuations occur, and radiation damping of compressive motions converts \( P_d V \) work into photon energy. The accretion stress in calculations having a net vertical magnetic field is found to be independent of opacity over the range explored and approximately proportional to the square of the net field. In calculations with zero net magnetic flux, the accretion stress depends on the portion of the total pressure that is effective in resisting compression. The stress is lower when radiation diffuses rapidly with respect to the gas. We show that radiation-supported Shakura-Sunyaev disks accreting via internal magnetic stresses are likely to have radiation marginally coupled to turbulent gas motions in their interiors.

Subject headings: accretion, accretion disks — instabilities — MHD — radiative transfer

1. INTRODUCTION

Because of the difficulty of removing angular momentum from infalling gas, material accreting on a black hole likely first accumulates in a disk supported against radial gravity by its rotation. The evolution of the disk is governed by the extraction of its angular momentum and the fate of the released gravitational energy. A possible structure for the flow was found by Shakura & Sunyaev (1973). They assumed angular momentum was transferred outward within the disk by an effective viscosity of unknown origin, proportional to the vertically averaged pressure at each radius. The released energy was converted to heat by the same viscosity, and the disk was cooled by vertical diffusion of photons to the surfaces. The disk was supposed to be time-steady, axisymmetric, and in vertical hydrostatic balance.

In the inner regions of Shakura-Sunyaev models with luminosities near the Eddington limit, radiation pressure is much larger than gas pressure and provides the main means of support in the vertical direction. If the stress that transports angular momentum is proportional to total pressure, the radiation-dominated regions are viscously (Lightman & Eardley 1974), thermally (Shakura & Sunyaev 1976), and convectively (Bisnovatyi-Kogan & Blinnikov 1977) unstable. These instabilities might prevent the formation of a steady disk. However, if the effective viscosity results from magnetic activity, buoyancy of the field may limit the stress to a value proportional to gas pressure alone, resulting in a thermally and viscously stable configuration (Sakimoto & Coroniti 1989). The structure of the inner parts of accretion flows onto black holes remains unknown.

A physical mechanism for transfer of angular momentum through disk gas is magnetorotational instability (MRI; Balbus & Hawley 1991). In this paper we examine the effects of MRI in radiation-dominated accretion disks. The MRI is a local linear instability, driven by exchange of angular momentum along magnetic field lines linking material at different distances from the black hole. Its fastest mode is axisymmetric and grows at \( \frac{1}{2} \) the orbital angular frequency \( \Omega \). The wavelength of fastest growth is fixed by a balance between Coriolis and magnetic tension forces and is approximately the distance \( 2\pi v_A/\Omega \) that Alfvén waves travel in an orbital period (Balbus & Hawley 1998).

In local three-dimensional MHD simulations without radiation, MRI leads to turbulence in which magnetic and hydrodynamic stresses transport angular momentum outward (Hawley, Gammie, & Balbus 1995). The magnitudes of the stresses depend on the geometry of the magnetic field. If the field has a net vertical flux, stresses are large and depend on the net flux. If the field instead has a net azimuthal flux, the stresses are weaker for the same pressure in the net component. If the field has zero net flux, stresses are weaker still, and after a few tens of orbits are independent of initial field strength (Hawley, Gammie, & Balbus 1996). Which of these magnetic configurations is most appropriate...
for disks around black holes may depend on nonlocal effects of outflow or buoyancy, which could lead to a buildup of net magnetic flux in accreting material.

The effects of MRI in radiation-dominated disks are uncertain. The range of linearly unstable wavelengths is unaffected by photon diffusion. However, when azimuthal magnetic pressure exceeds gas pressure and photons diffuse more than a vertical MRI wavelength \( \lambda_{\text{v}} = 2\pi v_{\text{Alf}} / \Omega \) per orbit, the growth rate of the axisymmetric MRI is reduced by a factor of roughly \( v_{\text{Alf}} / c_{\text{s}} \), where \( v_{\text{Alf}} \) and \( c_{\text{s}} \) are the vertical and azimuthal Alfvén speeds, and \( c_{\text{s}} \) is the gas acoustic speed (Blaes & Socrates 2001). Linear growth may be slow when magnetic pressure is greater than gas pressure, but much less than total pressure.

The MRI converts gravitational energy into magnetic and kinetic energy. Dissipation of the magnetic fields may heat the gas. Part of the kinetic energy may be converted directly to photon energy by radiative damping of compressive disturbances having wavelengths shorter than the distance that photons diffuse per wave period (Agol & Krolik 1998). In local axisymmetric MHD simulations, the MRI drives turbulence with density contrasts as great as the ratio of magnetic to gas pressure. Escape of radiation from the compressed regions damps the motions (Turner, Stone, & Sano 2002, hereafter TSS). These results suggest that magnetized turbulence may be important for heating, as well as angular momentum transfer in radiation-dominated accretion disks.

Here we extend the radiation MHD calculations of TSS to three dimensions, neglecting stratification. In three-dimensional calculations, the turbulence may reach a time-averaged steady state lasting many orbital periods. We examine the effects of radiation diffusion on the regeneration of magnetic field, the accretion stresses, and the damping of the turbulence.

2. DOMAIN, EQUATIONS SOLVED, AND NUMERICAL METHODS

We use the local shearing-box approximation (Hawley et al. 1995). The domain is a small patch of the disk, centered at the midplane a distance \( R_0 \) from the axis of rotation. Curvature along the direction of orbital motion is neglected, and the patch is represented in Cartesian coordinates corotating at the Keplerian orbital frequency \( \Omega_0 \) for the domain center. Coriolis and tidal forces in the rotating frame are included, while the component of gravity perpendicular to the midplane is neglected. The local coordinates \((x, y, z)\) correspond to distance from the origin along the radial, orbital, and vertical directions, respectively. The azimuthal and vertical boundaries are periodic, and the radial boundaries are shearing-periodic. Fluid passing through one radial boundary appears on the other at an azimuth that varies in time according to the difference in orbital speed across the box. The difference is computed using a Keplerian profile linearized about domain center. Because of the periodic boundary conditions, net magnetic flux is expected to be constant over time, provided the net radial flux is initially zero.

The equations of radiation magnetohydrodynamics are solved correct to zeroth order in \( \nu / c \). Relativistic effects are neglected, the flux-limited diffusion (FLD) approximation is used, and gas and radiation are assumed to be in LTE at separate temperatures. The equations are

\[
\frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{v} = 0 ,
\]

\[
\frac{D\mathbf{v}}{Dt} = -\nabla q + \frac{1}{4\pi} (\nabla \times \mathbf{B}) \times \mathbf{B} + \frac{\chi \rho}{c} \mathbf{F} - 2\rho \Omega_0 \times \mathbf{v} + 3\rho \Omega_0^2 \mathbf{x} ,
\]

\[
\frac{D\rho}{Dt} \left( \frac{E}{\rho} \right) = -\nabla \cdot \mathbf{F} - \mathbf{v} \cdot \mathbf{P} + \kappa \rho (4\pi B^2 - cE) ,
\]

\[
\frac{D\rho}{Dt} \left( \frac{\mathbf{e}}{\rho} \right) = -p \nabla \cdot \mathbf{v} - \kappa \rho (4\pi B^2 - cE) ,
\]

\[
\mathbf{F} = -\frac{c\Lambda}{\chi \rho} \nabla \mathbf{E} ,
\]

\[
\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B})
\]

(Mihalas & Mihalas 1984; Stone, Mihalas, & Norman 1992; Hawley et al. 1995). Here \( \rho, \mathbf{v}, \mathbf{e}, \) and \( \rho \) are the gas density, velocity, internal energy density, and pressure, respectively, and \( \mathbf{B} \) is the magnetic field. In the Coriolis term in the equation of motion (eq. [2]), \( \Omega_0 \) is the orbital angular frequency at domain center. Its direction is parallel to the rotation axis. In the tidal term, \( \mathbf{x} \) is a unit vector along the radial direction. The photons are represented by their frequency-integrated energy density \( E \), energy flux \( \mathbf{F} \), and pressure tensor \( \mathbf{P} \). Total opacity \( \chi \) is the sum of electron scattering opacity \( \sigma = 0.4 \text{ cm}^2 \text{ g}^{-1} \) and free-free absorption opacity \( \kappa = 10^{-4} \rho^{1/2} e^{-7/2} \text{ cm}^{-2} \text{ g}^{-1} \). In some calculations, scattering opacities higher or lower than the electron scattering value are used. The gas cools by emitting photons at a rate proportional to the blackbody value \( B = \sigma_0 T_b^4 / \pi \), where \( \sigma_0 \) is Boltzmann’s constant, \( T_b = p\mu / k \theta \rho \), the gas temperature, \( \mu = 0.6 \) is the dimensionless mean mass per particle, and \( \theta \) is the gas constant. In equation (5), the flux limiter \( \Lambda \) is equal to \( \frac{5}{4} \) in optically thick regions. Causality is preserved in regions where radiation energy density varies over optical depths less than unity by reducing the limiter toward zero (Levermore & Pomraning 1981). The equations are closed by assuming an ideal gas equation of state \( p = (\gamma - 1) e \), with \( \gamma = \frac{5}{3} \). Shocks are captured using an artificial viscosity in regions of convergence according to the standard prescription of von Neumann & Richtmyer (1950). We solve equations (1)–(6) by using a three-dimensional version of the Zeus code (Stone & Norman 1992a, 1992b) with its FLD module (Turner & Stone 2001).

In test calculations of magnetized turbulence in a shearing box, the fraction of the work done by shear that is lost from the domain through numerical effects is as great as 95% in ideal MHD and as little as 20% when an ohmic resistivity is included. We infer that the main numerical energy losses in the ideal-MHD calculations may occur in treating the magnetic terms in equations (2) and (6). For two of the calculations described in § 4, the internal energy scheme usually used in Zeus to solve equation (4) is therefore replaced by a partial total energy scheme. This is intended to capture as heat the energy that would otherwise be lost through numerical dissipation of magnetic fields. During the magnetic part of each time step, total energy is conserved. Immediately before the magnetic fields are updated, the gas internal energy density \( e \) in each zone is replaced by the sum
of gas internal, magnetic, and kinetic energy densities. The field is updated as usual, with time-centered EMFs computed by the method of characteristics (Hawley & Stone 1995). The same EMFs are used to find the Poynting fluxes $S = -(1/4\pi)(\mathbf{v} \times \mathbf{B}) \times \mathbf{B}$ of electromagnetic energy across zone faces. Total energy is moved from zone to zone according to these fluxes, using the difference form of

$$\frac{\partial \varepsilon_T}{\partial t} = -\mathbf{v} \cdot S.$$  (7)

Accelerations due to Lorentz forces are applied to the velocities in the usual way. Finally, the new magnetic and kinetic energies are subtracted from the new total energies, and the remainder is assigned to gas internal energy.

Results using the internal and partial total energy schemes were compared against a one-dimensional analytic solution for propagation of nonlinear torsional Alfvén waves in a uniform fluid (Sano 1998). The waves have moving nulls in the components of the field transverse to the direction of propagation. At the nulls, numerical losses of magnetic field may be rapid. Tests were carried out with longitudinal and transverse fields initially equal. The gas was either stationary on the grid or moving in the direction of wave propagation at 9 times the Alfvén speed. When gas and magnetic pressures were equal, results using the two schemes were similar. When gas pressure was 1% of magnetic pressure, numerical losses of field near magnetic nulls in the internal energy scheme led to longitudinal total pressure variations. Longitudinal motions grossly distorted the wave within a few oscillations. With the partial total energy scheme, total pressure was almost constant across the nulls, and the wave shape changed only slightly over 10 oscillations. For the case of stationary fluid, total energy decreased less than one part in $10^8$ over the same period. In additional tests, results for the Brio & Wu (1988) MHD Riemann problem differed little between the two energy schemes.

### 3. INITIAL CONDITIONS

Initial conditions are selected from a Shakura & Sunyaev (1973) model with parameters appropriate for an active galactic nucleus. The central mass is $M = 10^8 M_\odot$, luminous efficiency is $\eta = L/M c^2 = 0.1$, and the accretion rate $\dot{M}$ is 10% of the Eddington value $\dot{M}_E = 2.65 \times 10^{-9} (M/M_\odot) \eta^{-1} M_\odot$ yr$^{-1}$. In choosing the initial state only, the ratio of stress to total pressure is set to $\alpha = 0.01$. The domain is uniformly filled with gas having the density and midplane temperature of the Shakura-Sunyaev model at the central radius $R_0$. Radiation energy density is chosen for thermal equilibrium with the gas. The calculations are centered either at location I, where $R_0 = 67.8 r_G$ and radiation pressure is 125 times gas pressure, or at location II, where $R_0 = 177 r_G$ and radiation pressure is 10 times gas pressure. The gravitational radius $r_G = G M/c^2$. Location I is identical to location A discussed by TSS, while location II is considered in § 5 because the vertical MRI wavelength may be unresolved in calculations with zero net magnetic flux at location I. Conditions at the two locations are listed in Table 1. At these radii, the Shakura-Sunyaev model has large electron scattering optical depths $\tau_{es}$ and large effective free-free optical depths $\tau_{ff}^*$. The timescales for free-free energy exchange between gas and radiation are much less than the orbital periods, consistent with the assumption of initial thermal equilibrium. Additional sources of absorption opacity likely would have little further effect provided Thomson scattering remained the largest contribution to the total.

The height and width of the domain in all the calculations described here are set to the half-thickness $H$ of the Shakura-Sunyaev model. The depth along the direction of orbital motion is made 4 times greater. This allows the development of structures extended along the azimuthal direction, as seen in calculations without radiation effects (Hawley et al. 1995). Photons diffuse from midplane to surface in approximately 1/0.1 orbits in the Shakura-Sunyaev picture. At the standard electron scattering opacity, photons diffuse across the domain height in 50 orbits at both locations I and II.

Orbital velocities initially follow the linearized Keplerian profile required for radial force balance. Radial and vertical velocities in each zone are randomly chosen between $-1\%$ and $+1\%$ of the radiation acoustic speed.

#### 3.1. Diffusion of Radiation with Respect to Gas Fluctuations

Since photon diffusion can slow the linear growth of the MRI, it is possible that the fully developed turbulence may be affected also. The growth rate of the fastest axisymmetric linear mode is less than $\frac{\Delta}{2} \Omega$ when the azimuthal magnetic pressure exceeds the effective pressure. The effective pressure is equal to the gas pressure if radiation is absent or it diffuses quickly. On the other hand, the effective pressure is due to gas and radiation together if radiation pressure disturbances grow faster than they are erased by diffusion (Blaes & Balbus 1994; Blaes & Socrates 2001). In this section we consider the conditions under which radiation may provide support against magnetic forces in turbulence, so that fluctuations in density and radiation pressure are correlated.

From local MHD simulations with and without radiation, it has been found that turbulence driven by MRI is anisotropic. Fluctuations are thinner on average in the vertical direction than in the radial and azimuthal (Hawley et al. 1995, 1996; § 4 and 5). The characteristic size is the vertical MRI wavelength $\lambda_z = 2 \pi A_{z0}/\Omega$, and individual fluctuations typically last about one orbital period, $2 \pi/\Omega$. Photons may be expected to couple to the turbulence if the average vertical MRI wavelength is longer than the distance diffused per orbit, $D = [2 \pi c/(3 \chi \rho \Omega)]^{1/2}$. This condition for good coupling may be written

$$B_z^2 > \frac{2 \pi \Omega}{3 \chi}$$  (8)
or

$$|B_0| > 1.0 \times 10^8 G \left( \frac{M}{M_\odot} \right)^{-1/2} \left( \frac{R}{r_G} \right)^{-3/4}.$$  \hspace{1cm} (9)

The criterion is independent of the density provided electron scattering is the largest opacity.

4. UNIFORM VERTICAL MAGNETIC FIELD

In this section we describe results from simulations with initially uniform vertical magnetic fields. The domain is placed at location $I$, where radiation pressure is 125 times gas pressure. The grid consists of 32, 128, and 32 zones along the $x$-, $y$-, and $z$-directions, respectively.

4.1. Fiducial Calculation

For the fiducial calculation, the initial field strength is chosen so that the MRI wavelength is $\sim 1$ the domain height, and about twice the distance that photons diffuse per orbital period. The magnetic pressure is less than the gas pressure by a factor of 5 and less than the sum of gas and radiation pressures by a factor of 630.

During the first 2.5 orbits of the calculation, the initial random poloidal velocity perturbations lead to exponential growth of several linear modes. As expected, the mode growing fastest has four wavelengths in the domain height and is independent of radius. Its growth rate is 0.55 times the orbital angular frequency. When the radial magnetic field is comparable to the vertical field, inward- and outward-moving regions collide and the flow becomes turbulent. Turbulence continues to the end of the calculation at 50 orbits. The other calculations described in this section all pass through the same stages of linear growth and sustained turbulence.

The time evolution of the fiducial calculation is shown in Figure 1. At the start of the turbulent stage, total magnetic pressure increases by about 2 orders of magnitude mostly because of growth of the azimuthal field. Thereafter, magnetic pressure varies irregularly by an order of magnitude. Its time average between 10 and 50 orbits is 59% of initial gas plus radiation pressure. The variations are caused by repeated formation and disruption of channel flows, similar to those observed in calculations without radiation by Sano & Inutsuka (2001). During periods of field growth, the flow is nearly axisymmetric, and consists of layers of inward- and outward-moving fluid alternating along the vertical direction. Radial and azimuthal field strengths increase in lockstep, as in the linear axisymmetric MRI. Near peak field strength the square root of the domain-averaged squared vertical MRI wavelength may exceed the domain height. During periods of field decay, the flow is slower and less ordered, and the rms vertical MRI wavelength becomes shorter than the domain height. Like the magnetic pressure, the accretion stress has a well-defined saturated value. Its time average from 10 to 50 orbits is 36% of initial gas plus radiation pressure. When averaged over intervals longer than 10 orbits, the magnetic pressure and stress vary little with time. The mean ratio of the magnetic and hydrodynamic accretion stresses is 5.3, and angular momentum transfer is due largely to the magnetic stress.

Gas and radiation remain close to mutual thermal equilibrium throughout the fiducial calculation because of photon emission and absorption, while their pressures increase with time. Over 50 orbits, radiation pressure increases 12-fold, gas pressure almost by a factor of 2. The increases are due mostly to $P dV$ work done by the flow on the photons. Integrated from 10 to 50 orbits and over the domain, the compressive heating $\langle C \rangle = - \int dt \int (P + p) \nabla \cdot \mathbf{v} \, dx \, dy \, dz$ and artificial viscous heating $\langle A \rangle = - \int dt \int Q : \nabla \mathbf{v} \, dx \, dy \, dz$ are 15% and 6%, respectively, of the work $\langle W \rangle = \frac{1}{2} \int_0^t \int \Omega_0 H \int w_{xy} \, dy \, dz$ done by accretion stresses during this period. Here $Q$ is the tensor artificial viscosity, and the subscript $X$ indicates integration over the radial boundary (Hawley et al. 1995). Defining total energy $\Gamma$ as the sum of radiation, internal, magnetic, kinetic, and gravitational potential energies in the local frame, the total energy increase between 10 and 50 orbits is just 21% of the energy added to the box by accretion stresses. The remainder of the work done is removed through numerical losses of magnetic and kinetic energy. The density contrast $\rho_{\text{MAX}}/\rho_{\text{MIN}}$ is more than an order of magnitude during the first few orbits of turbulence but decreases over time, reaching about 2 at 50 orbits.
Radiation diffusion is an excellent approximation throughout the calculation. At all times, the zone with the lowest density has an optical depth greater than 19. The components of the Eddington tensor differ from their isotropic values by less than $10^{-6}$, and flux limiting is unimportant. The coupling between turbulent fluctuations in gas and radiation varies, because of the changes in the strength of the magnetic field, but is generally good. The ratio of the vertical MRI wavelength to the diffusion length, computed using the domain-averaged vertical magnetic pressure, ranges from 4, when the field is weakest, to 13, when the field is strongest. Thus, equation (8) is satisfied throughout the evolution. The time-averaged rms fluctuation in radiation pressure is comparable to the fluctuation in magnetic pressure, indicating that photons are sufficiently coupled to the turbulence to provide pressure support against magnetic forces.

The ratio of magnetic accretion stress to vertical magnetic pressure ranges from 8 to 20 and has time average 12.5. The ratio varies in part due to formation and breakup of channel flows. Radial and azimuthal fields grow in the channel flows through MRI, leading to increases in the ratio of domain-flows. Radial and azimuthal fields grow in the channel flows ratio varies in part due to formation and breakup of channel pressure ranges from 8 to 20 and has time average 12.5. The forces.

The parameters for all the calculations with initially uniform vertical fields are shown in Table 2. Each calculation is given a label containing the letter V to indicate that its magnetic field has a net vertical flux. The labels of those including radiation effects start with R. The labels of those without the radiation terms start with N. Each label includes a number indicating the ratio of the domain height to the initial MRI wavelength, which fixes the magnetic field strength. For example, the fiducial calculation has label RV4. Suffixes indicate a higher opacity ($h$), a lower opacity ($l$), and a change in the seed used in generating the random initial poloidal velocities ($s$). Initial radiation, magnetic, and gas pressures are listed relative to the gas pressure at location I.

The results of the vertical field calculations are summarized in Table 3. The domain average of any quantity $q$ is indicated by $\langle q \rangle$, the time and domain average by $\langle \langle q \rangle \rangle$. The rms values are computed by the square root of the domain average of the square. Time averages in Table 3 are taken between 10 and 50 orbits after the start of each run. Column (1) lists the label of the simulation; column (2), the rms ratio of the vertical MRI wavelength to the distance that photons diffuse per orbit; column (3), the ratio of magnetic stress to vertical magnetic pressure; column (4), the total accretion stress $w_{\text{xy}}$, in units of the gas plus radiation pressure at location I; column (5), the density contrast; column (6), the compression heating $\langle \langle C \rangle \rangle$; and column (7), artificial viscous heating $\langle \langle A \rangle \rangle$ between 10 and 50 orbits, as fractions of the work $\langle \langle W \rangle \rangle$ done by accretion stresses during this period.

### 4.2. Magnetic Field and Accretion Stress

Over the range of opacities explored here, radiation diffusion has little effect on the accretion stress (Fig. 2). Results from the fiducial calculation are shown along with those from versions with scattering opacity increased a hundredfold (RV4h) and decreased fourfold (RV4l), and radiation pressure replaced by an equal amount of additional gas pressure (NV4). The four calculations have the same initial magnetic field. The total stresses, averaged over the domain and over time between 10 and 50 orbits, are 0.36, 0.36, 0.32, and 0.29 times the initial gas plus radiation pressure. The differences in mean stress among the four are much less than the range of time variation in each. Stresses in the calculation that includes gas pressure only are similar to those in the runs including both gas and radiation. The time-averaged rms ratio of the diffusion scale to the MRI wavelength is 1/71 in the high-opacity version, 1/7 in the fiducial
version, and 1/3.4 in the low-opacity version. In these calculations having a net vertical magnetic flux and strong to marginal coupling between gas and radiation, the stresses vary little with the diffusion rate.

The dependence of the mean total accretion stress on initial magnetic pressure is shown in Figure 3. The relationship is approximately linear over the limited range explored, with the stress about 200 times the initial magnetic pressure. The uncertainty in the positions of the points may be gauged by comparing the two open squares near horizontal position $C_0^2.8$. These are from RV4l, and a calculation RV4ls identical except that the initial poloidal velocity perturbations are chosen using a different random number seed. The differences between results with and without radiation in Figure 3 are about as large as the differences resulting from the changed perturbation.

In calculations carried out by Hawley et al. (1995), the saturation level is proportional to the net vertical magnetic field rather than to the vertical magnetic pressure (their Fig. 6). The discrepancy may be due in part to the longer integration time employed here. Longer integrations allow better estimates of the time-averaged values of the fluctuating stresses. The results in Figure 3 are from runs lasting 50 orbits, whereas the previous calculations lasted 7–16 orbits.

The mean ratios of magnetic to hydrodynamic stress in our calculations are mostly about 5, and the range is from 2.0 to 12. There is no clear trend in the ratio of magnetic to hydrodynamic stress with field strength or opacity.

The time variations in the accretion stress, associated with formation and breakup of channel flows, decrease in relative amplitude with decreasing field strength. In calculations with 12 and 16 wavelengths initially filling the domain height, no strong channel flows are observed on the largest scale. In the weakest-field calculations NV16, RV16, and RV16l, the MRI wavelength is initially only two grid zones. However, during the turbulent stage, the field is stronger than initially because of squeezing and folding. The time-averaged rms vertical MRI wavelengths in NV16, RV16, and RV16l are 10, 8, and 7 zones, respectively, and are probably adequately resolved. The large stress variations occur

### Table 3

| Label      | Coupling $\sqrt{\langle \langle B_z^2 \rangle \rangle / (2\Omega_0 / 3\chi)}$ | Field Geometry $\langle -B_z B_z / 4\pi \rangle / \langle B_z^2 / 8\pi \rangle$ | Total Stress $\langle \langle w_{xy} \rangle \rangle / (P_0 + \rho_0)$ | Density Range $\langle (\rho_{MAX} / \rho_{MIN}) \rangle$ | Compression Heating $\langle (C) \rangle / \langle (W) \rangle$ | Artificial Viscous Heating $\langle (A) \rangle / \langle (W) \rangle$ |

**Note.**—Results are averaged between 10 and 50 orbits.

The variations in the accretion stress with time in simulations with initially uniform vertical magnetic fields. Results are shown from calculations without radiation (top; NV4), with scattering opacity 100 times the electron scattering value (second from top; RV4h), with the usual opacities (third from top; RV4), and with scattering opacity 1/4 of the electron scattering value (bottom; RV4l). Magnetic stresses are indicated by solid lines, and hydrodynamic stresses by dotted lines. In each case, the total accretion stress averaged from 10 to 50 orbits is indicated at upper right. The stresses are shown in units of the initial gas plus radiation pressure.
only in the calculations having vertical MRI wavelength comparable to the box height.

Overall, in the simulations with net vertical flux, the saturated field strength and accretion stress are similar with and without radiation effects, whether the photons are strongly or marginally coupled to the flow.

4.3. Turbulent Fluctuations

Large density contrasts may be expected if magnetic pressure is greater than gas pressure, and radiation diffuses rapidly. As shown in Figure 4 and Table 3, the density range is larger in the fiducial calculation RV4 than in the version NV4 with the radiation replaced by extra gas pressure. Among radiation runs with identical initial magnetic fields, the density contrast is greater in those having weaker coupling of photons to gas. Run RV4l, in which the mean vertical MRI wavelength is 3.4 times the diffusion length, has a time-averaged density contrast $\left(\langle \rho_{\text{MAX}}/\rho_{\text{MIN}} \rangle \right) = 11.5$. The fiducial calculation RV4 has a similar mean vertical MRI wavelength, a diffusion length half as great, and a mean density contrast of 3.6. In the high-opacity run RV4h, the diffusion length is 10 times shorter again. The mean density contrast is about 2 and differs little from that in the run NV4 with radiation replaced by extra gas pressure. Among the calculations listed in Table 2, the time-averaged rms density fluctuation is well correlated with the logarithm of the time-averaged density contrast, indicating that these two quantities are about equally good measures of the overall density distribution.

Two calculations differing in vertical magnetic pressure can have the same degree of coupling, provided they differ in opacity in the inverse proportion. The squared ratio of the vertical MRI wavelength to the diffusion scale is proportional to $B_z^2/C_{36}^2$, as shown by equation (8). At a given level of coupling, the density contrast is found to be greater in the calculation with the stronger magnetic field (Fig. 5). For large density contrasts, it is necessary that the mean

Fig. 3.—Dependence of total accretion stress on initial magnetic pressure in calculations starting with uniform vertical magnetic fields. The stress is averaged over the domain and from 10 to 50 orbits. Calculations NV2.5 through NV16 have radiation replaced by extra gas pressure. Their results are marked by open circles. The best straight-line fit for the results without radiation is shown by a solid line and has slope 0.82. The range of slopes allowed by the scatter of the points is $0.04$. Calculations RV2.5 through RV16 include radiation effects with normal opacities and are shown by filled circles. The best straight-line fit (dotted line) has slope 0.88 $\pm 0.04$. Calculations RV2.5l through RV16l have scattering opacity 4 times less and are shown by squares. The best-fit line for the low-opacity results (dashed line) has slope 1.04 $\pm 0.04$.

Fig. 4.—Snapshots of the density distribution on the domain faces at 20 orbits, in three calculations with initially uniform vertical magnetic fields. Left, Calculation without radiation NV4; center, the high-opacity version RV4h; and right, the fiducial calculation RV4. Radius $x$ increases to the right, azimuth $y$ into the page, and height $z$ upward. The common logarithmic density scale spans 1 decade, while the density contrast in the fiducial calculation at this time is a factor of 24.
magnetic pressure be at least comparable to the gas pressure but not so large that the vertical MRI wavelength is longer than the radiation diffusion length. At fixed gas pressure, the maximum density contrast is attained near the magnetic pressure for which the coupling is marginal.

The density contrast in the fiducial calculation decreases over time (Fig. 1) as the pressure rises. Gas and radiation pressures increase steadily because of dissipation of energy released through the accretion stresses, whereas magnetic pressure, averaged over periods of 10 orbits, varies little during the turbulent stage. At 50 orbits, radiation pressure is 12 times higher than initially. In a weaker field calculation RV16, the density range near the end of the turbulent stage is similar to that near the beginning. The mean accretion stress here is 14 times lower, and radiation pressure increases only 1.8-fold over 50 orbits. The density range depends on the pressure available to resist squeezing by the magnetic field.

The effective equation of state of fluctuations in the turbulence depends on the degree to which the radiation is coupled to the gas. When the scattering opacity is large and gas and photons travel together, the combined fluid has an adiabatic equation of state with exponent very close to 4/3 (Fig. 6, second from top). When the distance that photons diffuse per orbit is comparable to the vertical MRI wavelength, temperature excursions in the gas are damped by rapid emission or absorption, followed by escape of photons to other regions. In this case the gas is close to isothermal (Fig. 6, bottom). At the highest densities, radiation is partly trapped, and the temperature rises slightly above that of the rest of the flow.

During the fiducial calculation RV4, the energy density in gas plus radiation increases by 11 times its initial value. Heating is fastest when the magnetic field strength and density contrast are large (Fig. 1). Three terms in the energy equations (3) and (4) may lead to net increases in the total internal energy in the domain. These are the terms representing compression of radiation and of gas, and artificial viscous heating of the gas. Net compression heating may be found in shocks. It can also occur when regions of the flow are squeezed, then cool as radiation diffuses out into the surroundings. Because diffusion is thermodynamically irreversible, this mechanism leads to permanent conversion of $PdV$ work into photon energy. Work done on the gas is largely converted into radiation energy within a fraction of an orbit by emission of photons, and it can diffuse away also. In the fiducial calculation, the net increase in total internal energy because of the two compression terms is 15% of the work done on the flow by accretion stresses. The increase because of artificial viscous heating is 6% of the energy input. In the calculation NV4 with radiation replaced by additional gas pressure, diffusion is absent and the compression heating rate is lower. The contributions from compression and artificial viscosity are 2% and 8%, respectively. Among the calculations listed in Table 3, the largest ratio of compression heating to energy input is 26% and occurs in the low-opacity weak-field run RV16l, for which the coupling of photons to gas is weakest. The average compression heating fraction varies with the logarithm of the density contrast in these calculations (Fig. 7). The tight correlation between $PdV$ heating efficiency and density range indicates that the criteria for strong compression
heating are similar to those for large density contrast outlined in § 4.3.

The low ratios of the heating rates to the work done in each of the simulations listed in Table 3 mean that the majority of the released energy vanishes and is never deposited in the internal energy of gas or photons. In resistive MHD calculations without radiation, up to 80% of the work done is dissipated by ohmic heating (Sano & Inutsuka 2001). Losses of magnetic field without corresponding heating may be a major sink of energy in ideal MHD calculations. Such losses can occur through numerical diffusion and through advection of opposing magnetic fields into a single grid zone. To examine the importance of numerical magnetic losses for the energy balance here, we made a version of the weakest-field low-opacity radiation calculation RV16l, using the partial total energy scheme described in § 2. With this scheme, total energy is conserved during the magnetic field update and Lorentz acceleration portion of each time step. Magnetic energy that disappears during the field update is placed in the internal energy of the gas. In the version of run RV16l using this scheme, the increase in total energy between 10 and 50 orbits is equal to 90.6% of the work done by the accretion stresses. The contributions from compression heating, artificial viscous heating, and numerical magnetic losses are 23.6%, 5.51%, and 61.5% of the work done, respectively. The majority of the remaining 9.4% may disappear through losses of kinetic energy in the momentum transport substep. The mean total stress, 0.0204 times the initial gas plus radiation pressure, differs only slightly from that in the version using the ordinary internal energy scheme. The sum of gas and radiation pressures increases 3.4-fold over 50 orbits, whereas in the version RV16l using the usual internal energy scheme the increase is only 60%.

Gas and radiation remain near thermal equilibrium despite the additional heating, because of the emission and absorption of photons. In a version of the fiducial run RV4 using the partial total energy scheme, the extra heating leads to such rapid increases in gas and radiation pressures that the flow becomes almost incompressible after a few orbits of turbulence, and \( PdV \) heating largely ceases. These results indicate that numerical losses of magnetic energy must be considered when using MHD simulations to examine the energy budgets of accretion disks.

5. FIELDS WITH ZERO NET FLUX

Magnetic fields with net vertical flux, such as those used in § 4, cannot be completely destroyed in the shearing-box approximation because of the periodic boundaries. The mean pressure in the vertical component of the field cannot fall below its initial value. In this section we consider fields with zero flux. Under these conditions, dissipation and dynamo action may lead to fields either weaker or stronger than initially. The starting magnetic field chosen has strength independent of position, and direction varying with radius \( \rho \). Its components are

\[
B_z = B_0 \sin \left( \frac{2\pi \rho}{H} \right),
\]

\[
B_r = B_0 \cos \left( \frac{2\pi \rho}{H} \right),
\]

\[
B_\theta = 0.
\]

Field strength \( B_0 \) is such that the MRI wavelength is \( \frac{1}{4} \) of the domain height \( H \).

In calculations with zero net magnetic flux centered at location I, field strength declines during the turbulent stage until the rms vertical MRI wavelength is less than two grid zones and turbulence ceases. The true saturation level may correspond to a vertical MRI wavelength less than the grid spacing. The rest of the calculations with zero net flux are carried out at location II, where radiation pressure is 10 times gas pressure (§ 3). To better resolve the MRI wavelength at weak magnetic field strengths, a grid consisting of \( 64 \times 256 \times 64 \) zones is used except where noted. The parameters for the calculations with zero net magnetic flux are listed in Table 4, and some time- and domain-averaged results are shown in Table 5. Initial pressures in Table 4 are written in terms of the gas pressure at location II.

5.1. Magnetic Field and Accretion Stress

We first examine how field strength in the turbulence depends on gas pressure in the absence of radiation. The results are then compared against similar calculations including coupling to photons.

For compressible flows, the gas pressure gradient term in the equation of motion (eq. [2]) can affect the development of the magnetic field. Linear perturbations have a compressive part if the background field includes an azimuthal component (Blaes & Balbus 1994; Kim & Ostriker 2000). Pressure effects may be present also in well-developed turbulence. In local shearing-box calculations with zero net magnetic flux, the accretion stress at saturation is proportional...
to the fourth root of the gas pressure (T. Sano 2003, in preparation).

To compare directly with the radiation results described next, we performed two calculations without radiation, using different initial gas pressures. In run NS4, the radiation pressure at location II is replaced by an equal amount of additional gas pressure. In run NS4g, no extra gas pressure is added, and the initial pressure is 11 times less. Results are shown in Figure 8 (top). The total accretion stress, averaged from 30 to 80 orbits, is 0.00490 in the higher pressure calculation NS4 and 0.00124 in the lower pressure calculation NS4g. The stresses are measured in units of the initial gas pressure. In both cases, the magnetic part of the stress is about 3 times the hydrodynamic part. Gas pressure increases over time in both runs, because of dissipation of the turbulence. The mean gas pressures over the same period are 1.08 and 0.209, respectively, in the same units. During this interval, run NS4 has mean gas pressure 5.2 times greater than NS4g, and mean stress over the same period are 1.08 and 0.209, respectively, in the high-opacity calculation RS4h.

The effects on field strength of the coupling between radiation and gas may be seen from Figure 8 (bottom). In the high-opacity calculation RS4h, the scattering opacity is 100 times the electron scattering value, the vertical MRI wavelength is initially 20 times the diffusion scale, and the photons are thoroughly coupled to the flow throughout the run. The field strength is similar to that in run NS4, in which radiation is replaced by extra gas pressure. By contrast in the standard radiation calculation RS4 the scattering opacity is set to the usual electron scattering value. Initially the vertical MRI wavelength is about twice the distance that radiation diffuses per orbit, and photons are moderately coupled to the gas. The domain-mean total magnetic pressure is always greater than initially because of stretching along the azimuthal direction. However, the mean pressure in the vertical component of the field declines over the first 10 orbits of turbulence and thereafter remains less than its initial value. From 30 orbits onward, the vertical MRI wavelength is less than the diffusion scale, and photons are weakly coupled to disturbances. The magnetic field is weaker than in the high-opacity case. Averaged from 30 to 80 orbits, the total stress is 0.00208 in RS4, and 0.00649 in the high-opacity version RS4h. Field strength in the standard-opacity run RS4 is comparable to that in the low gas pressure run NS4g without radiation. The two calculations differ in that gas pressure rises more slowly with time in RS4. Heating of the gas is almost entirely offset by the net emission of radiation required to maintain thermal equilibrium. In run NS4g, radiation effects are not included, and the gas has no means of cooling.

To examine possible effects of the choice of initial magnetic field, we have also carried out a high-opacity run initialized with the density, pressure, and magnetic field distributions from the standard-opacity calculation RS4 at 90 orbits. Over 10 orbits, the field grows in strength until it is similar to that in the high-opacity calculation RS4h. The total stress, averaged from 10 to 30 orbits after the increase in opacity, is 0.00525.

In these five calculations, the MRI generates fluctuations in magnetic fields that lead to fluctuations in gas and radiation pressures. If radiation diffuses quickly, the radiation pressure is almost spatially uniform, and gradients are smaller than those in gas pressure. Gas pressure gradients alone resist magnetic fluctuations. On the other hand, when radiation diffuses slowly, the spatial distributions of gas and radiation are quite similar. The radiation pressure gradient...
works in the same way as the gas pressure gradient. In this case, the effective thermal pressure is the sum of the gas and radiation pressures. The saturation amplitude is found to be larger in the calculations with larger effective pressure.

The magnetic field is patchy in the standard radiation run RS4 (Fig. 9, top). The vertical extent of the patches is typically \( \frac{1}{10} \) the domain height \( H \), similar to the rms vertical MRI wavelength. Domain-mean magnetic pressure also varies over time, by almost an order of magnitude. The vertical magnetic pressure at 70 orbits is less than the initial total pressure by a factor of 28,000. At 120 orbits, the ratio is only 5200. This variation is probably not related to a change in compressibility. The magnetic field is more nearly azimuthal when it is weaker. The field geometry varies with magnetic pressure in a similar way to the calculations with high opacity, RS4h, and without radiation, NS4 and NS4g, within the range of magnetic pressure the calculations have in common. In the lower resolution versions of RS4h and NS4, the vertical magnetic pressure is about 3 times less at the same magnetic stress. This effect may be due to marginal spatial resolution.

We conclude that the accretion stress depends on gas pressure in the absence of radiation effects. If radiation dominates total pressure, the stress depends on both gas pressure and opacity. When coupling between gas and radiation is strong, radiation pressure plays a role similar to extra gas pressure, and the stress is large. When photons are decoupled from turbulent motions and compression is resisted largely by gas pressure, the stress is less.

5.2. Turbulent Fluctuations

The gas is nearly isothermal on small scales in the standard radiation run RS4, despite small-scale density fluctuations (Fig. 9, middle and bottom). Photons readily diffuse between the regions of compression and expansion, so that the radiation temperature is close to uniform. Gas and radiation temperatures differ by less than 1% because the timescale for thermal equilibration is much less than the orbital period. In the high-opacity calculation RS4h, the vertical MRI wavelength is longer than the diffusion scale, the effective equation of state is that of a \( \gamma = \frac{4}{3} \) gas, and temperature fluctuations are comparable in magnitude to density fluctuations. The calculations NS4 and NS4g without radiation show the expected adiabatic relation between temperature and density.

In the standard radiation run RS4, the density is lowest in regions having magnetic pressure greater than gas pressure. Where the magnetic field is weak, the density is near its mean value (Fig. 10). The situation is different in the high-opacity run RS4h, where radiation pressure resists compression even in regions with magnetic pressure exceeding gas pressure. The mean density contrast in RS4h is 1.52, whereas that in RS4 is 2.04 despite the weaker magnetic field (Table 3). In the calculation NS4g with radiation removed, the mean density range between 30 and 80 orbits is 1.71, intermediate between those in RS4 and RS4h. The density contrast may be less than in RS4 because gas pressure doubles during the first 30 orbits in NS4g, because of dissipation of the turbulence without net emission of photons.
In the calculation NS4 with radiation replaced by extra gas pressure, the gas pressure is greater than the magnetic pressure in every zone, and the mean density contrast 1.37 is small. In summary, density fluctuations in the calculations with zero net magnetic flux are largest when radiation is weakly coupled to the disturbances and magnetic pressure is greater than gas pressure.

5.3. Heating

Of the four calculations with zero magnetic flux listed in Table 4, only one shows sustained net compression heating. In the standard radiation run RS4 between 30 and 80 orbits, the total compression heating is equal to 21% of the energy added to the domain via accretion stresses (Table 5). In the remainder of the simulations with zero magnetic flux, $P \, dV$ heating is ineffective because of the absence or slow rate of radiation diffusion. Compressive motions are instead damped by artificial viscosity. In the run NS4g with radiation removed, 18% of the energy released by accretion stresses is dissipated through artificial viscous heating. Artificial viscosity is about as important in NS4g as compression heating in RS4. The artificial viscous heating in runs RS4h, NS4, and NS4g is partly balanced by net expansion cooling, indicating pressures are greater on average during expansion than during compression. Of the four calculations, only the standard radiation run RS4 shows substantial heating by a physical mechanism.

6. DISCUSSION

The variation of stress with opacity, the large density fluctuations, and the radiation damping described in §§ 4 and 5 are all related to the amount of coupling between gas and photons. When the vertical MRI wavelength is longer than the diffusion scale and the inequality in equation (8) is satisfied, the effective pressure that resists compression by magnetic forces is due to gas and radiation pressures together. When the MRI wavelength is shorter than the diffusion scale, the effective pressure is due to gas alone. In regions of accretion disks where radiation pressure greatly exceeds gas pressure, the degree of coupling may be a crucial factor in determining the properties of the turbulence.

The orientation of the magnetic field may be measured by the ratio $s$ of the magnetic stress $\langle -B_i B_j / 4\pi \rangle$ to the vertical magnetic pressure $\langle B_z^2 / 8\pi \rangle$. This ratio is similar in calculations with and without radiation, and with gas-photon coupling good or marginal. The time-averaged values of $s$ in the calculations listed in Tables 3 and 5 are plotted in Figure 11. In stratified isothermal simulations by Miller & Stone...

Fig. 9.—Results from the standard calculation with radiation and zero net magnetic flux. Each panel is a slice through the midplane at 80 orbits. Radius increases upward, distance along the orbit to the right. Top, Magnetic stress; middle, density; and bottom, radiation temperature. The color scales are linear. The distance that photons diffuse per orbit at the mean density is the radial extent of the domain.
Similar ratios of magnetic stress to vertical magnetic pressure were found within 2 scale heights of the midplane. The ratio in each of these cases is between 8 and 20. The characteristic vertical scale of turbulent fluctuations in these calculations is the rms vertical MRI wavelength \( \lambda_z \). Because of the small range of field orientations \( s \), the characteristic vertical scale may be approximately determined from the accretion stress and gas density.

If magnetic fields in radiation-supported Shakura-Sunyaev disks have orientations similar to those observed here, then the vertical MRI wavelength \( \lambda_z \) may be a fixed fraction of the distance that photons diffuse per orbit \( l_D \).

\[
\left( \frac{\lambda_z}{l_D} \right)^2 = \frac{3 \chi \langle B_z^2 \rangle}{2 \pi \Omega}.
\]

(13)

When a disk is in inflow equilibrium and its \( R - \phi \) stress is primarily due to magnetic forces, conservation of angular momentum requires

\[
\langle -B_x B_y \rangle H = \dot{M} \Omega R_T,
\]

(14)

where \( R_T \) includes relativistic corrections and the effect of the overall flux of angular momentum through the disk. If the MRI-driven turbulence leads to magnetic fields with fixed orientation \( s \), the angular momentum conservation equation (14) constrains the vertical magnetic pressure, and hence the squared coupling ratio is

\[
\left( \frac{\lambda_z}{l_D} \right)^2 = \frac{3 \chi \dot{M} R_T}{s R^2}.
\]

(15)

Thermal equilibrium together with vertical hydrostatic balance between gravity and radiation pressure determines the disk half-thickness \( H \) in terms of the accretion rate. Using this relation yields

\[
\frac{\lambda_z}{l_D} = \left( \frac{8 \pi R_T R_z}{s R^2} \right)^{1/2},
\]

(16)

where \( R_R \) is the correction factor that is the energy conservation analog of \( R_T \) and \( R_z \) is the relativistic correction to the vertical gravity. For field orientation \( s = 8 \) and unit correction factors, the MRI wavelength is 1.8 times the diffusion scale. For \( s = 20 \), the ratio is 1.1.

Thus, when a disk is in hydrostatic, thermal, and inflow equilibrium and its vertical support is primarily radiative, we can expect the photons to be marginally coupled to the MHD turbulence in the interior. This result holds whether the stress scales with total pressure, gas pressure alone, or some combination, as the stress law is not specified in the derivation. However, if an uneven dissipation distribution makes the disk thinner than in the simplest picture of complete radiation support (Svensson & Zdziarski 1994), the coupling near the midplane may be better than indicated.
pressures. A dotted line marks calculations with high opacity, where it is set to the sum of gas and radiation calculations discussed by TSS are shown also by plus signs. Other symbols effective pressure in the calculations listed in Tables 2 and 4. Results of tical flux (pressure. The standard-opacity radiation runs with net ver-
in calculations with magnetic pressure greater than effective turbulence are summarized in Figure 12. Contrasts are large here. Given the strong connection between coupling quality and compressibility that we have seen and the further likely connection between compressibility and magnetic dissipation, the quality of coupling may be self-regulated in some fashion.

The effects of diffusion on density contrasts in the turbulence are summarized in Figure 12. Contrasts are large in calculations with magnetic pressure greater than effective pressure. The standard-opacity radiation runs with net vertical flux (small filled circles) are plotted using gas pressure for effective pressure in all cases. However, in those with the stronger magnetic fields, longer MRI wavelengths mean that radiation is more tightly tied to the turbulence. The correct effective pressure is intermediate between the gas and total pressures. If effective pressure is as large as total pressure, the case with strongest magnetic field is shifted 2.9 decades to the left. Cases with weaker fields have weaker gas-radiation coupling and are to be shifted shorter distances to the left. Also plotted are results from calculations by TSS, listed in their Table 2. Togethe
together, the data indicate density contrasts can be as great as the ratio of magnetic to gas pressure provided radiation is not well coupled to gas. In the axisymmetric calculations by TSS, the magnetic field geometry in the transient turbulence is controlled by the initial condition. At a fixed magnetic pressure, fields more nearly aligned with the azimuthal direction result in fluctuations with shorter vertical wavelengths. Weaker coupling of radiation to gas over these smaller scales means smaller effective pressures, so that magnetic forces produce greater compression. In the three-dimensional calculations, the field geometry is determined by the action of the turbulence. The field is found to be more inclined from the azimuthal than in the fiducial case of TSS, resulting in smaller density ranges at similar magnetic pressures. Density contrasts greater than 20 are demonstrated here in long-lasting three-dimensional turbulence.

7. SUMMARY AND CONCLUSIONS

We carried out three-dimensional MHD calculations of local patches of a radiation-dominated accretion disk. The vertical component of gravity was neglected, and periodic boundaries were used in the vertical direction. Magneto-rotational instability led to magnetized turbulence in which Maxwell stresses transported angular momentum outward. A number of basic differences between results with and without radiation are caused by the diffusion of photons with respect to the material. When opacity is high enough that radiation is locked to gas over the length and timescales of fluctuations in the turbulence, the accretion stress, density contrast, and dissipation differ little from those in the corresponding calculations with radiation replaced by extra gas pressure. However, when radiation diffuses each orbit a distance that is comparable to the rms vertical MRI wave-
length, radiation pressure is less effective in resisting squeezing. Larger density fluctuations occur, and a nonlinear version of the radiation damping mechanism outlined by Agol & Krolik (1998) converts $PdV$ work into photon energy.

The accretion stress is found to depend on the vertical magnetic flux present. If the net vertical field is large enough so the corresponding MRI wavelength is at least 1/16 the domain height, the time-averaged stresses are similar whether photons and gas are strongly or marginally coupled. If there is no net vertical magnetic flux, the field strength depends on the opacity and is greater when gas and radiation are dynamically well coupled. Over a wide range of field strengths, the ratio of accretion stress to vertical magnetic pressure is near the value required in radiation-supported Shakura-Sunyaev models to make the vertical MRI wavelength equal to the distance $\sqrt{\alpha}H$ that photons diffuse per orbit. These results indicate photons may be marginally coupled to turbulent eddies in Shakura-Sunyaev disks accreting via internal magnetic stresses. Our work is not the first indicating that magnetic stress may scale with gas pressure alone rather than total pressure. However, previous suggestions were made either on the basis of an ad hoc search for ways to cure instabilities besetting conventional disk models (Sakimoto & Coroniti 1981; Taam & Lin 1984) or on the basis of a limitation to the magnetic field strength placed by buoyancy (Stella & Rosner 1984; Sakimoto & Coroniti 1989). The new point here is that the inability of the magnetic field strength to track the total pressure is due to photon diffusion effects.

Density contrasts greater than an order of magnitude are observed in cases in which magnetic pressure exceeds gas pressure, and photons partly decouple from the gas. Such large density variations may alter the bulk radiation transport rate, the effective optical depth, and the spectrum emerging from the disk photosphere. The density fluctuations involve repeated compression and expansion of fluid elements. Diffusion of photons from compressed regions converts up to $1/4$ of the released gravitational energy to radiation energy.

In the simulations discussed here, the heating results in secular increases in radiation pressure, as the disk surface is omitted and there is no means for cooling the flow.
Stationary disk structures might be found using calculations including radiation losses. An accurate balance between heating and cooling can be obtained in such calculations only if total energy is conserved. In unstratified calculations using a standard internal energy scheme, the majority of the released energy disappears through numerical losses of magnetic field. In calculations conserving total energy during the magnetic substep, approximate overall energy conservation is observed. Such a partial total energy scheme may be adequate for use in calculations of disk vertical structure. It is likely that the rates at which disks heat and cool depend on the disk thickness. Calculations in which the thickness is allowed to vary may be useful in addressing the question of the thermal stability of radiation-dominated disks.
