(Dated: August 1, 2016)

We present a relativistic formulation of the quantum Hall effect on Haldane sphere. An explicit form of the pseudopotential is derived for the relativistic quantum Hall effect with/without mass term. We clarify particular features of the relativistic quantum Hall states with the use of the exact diagonalization study of the pseudopotential Hamiltonian. Physical effects of the mass term to the relativistic quantum Hall states are investigated in detail. The mass term acts as an interpolating parameter between the relativistic and non-relativistic quantum Hall effects. It is pointed out that the mass term unevenly affects the many-body physics of the positive and negative Landau levels as a manifestation of the “parity anomaly”. In particular, we explicitly demonstrate the instability of the Laughlin state of the positive first relativistic Landau level with the reduction of the charge gap.

I. INTRODUCTION

Dirac matter has attracted considerable attention in condensed matter physics for its novel properties and recent experimental realizations in solid materials. In contrast to normal single-particle excitations in solids, Dirac particles exhibit linear dispersion in a low energy region and continuously vanishing density of states at the charge-neutral point 1. These features are actually realized in graphene 2,3 and on topological insulator surface 4. Besides, in the presence of a magnetic field, the relativistic quantum Hall effect was observed in graphene 5,6 and also on topological insulator surface recently 7,8,9.

One of the most intriguing features of the relativistic quantum Hall effect is the effect of mass term; in the non-relativistic quantum Hall effect, the mass parameter just tunes the Landau level spacing, while in the relativistic quantum Hall effect the mass term is concerned with interesting physics such as the semi-metal to insulator transition and the time reversal symmetry breaking of the topological insulators 10. In experiments, disorder and interaction with a substrate in the atomic layer of graphene cause the asymmetry in the two sublattices of a honeycomb structure to induce a mass term 11,12, and magnetic doping in topological insulators yields a massive gap of the surface Dirac cone 13. Interestingly, in the presence of an external magnetic field, the mass term brings the physics associated with the “parity anomaly” 14: in the absence of a magnetic field, the mass term does not change the equivalence between the positive and negative energy levels 15, while in the presence of a magnetic field, asymmetry occurs between the positive and negative energy levels depending on the sign of the mass parameter 16 (see Fig.1).

In this paper, we establish a relativistic formulation of the quantum Hall effect on a two-sphere and perform a first investigation of the “parity anomaly” in the context of the relativistic many-body physics. For concrete calculations, the spherical geometry called Haldane sphere 17 is adopted. Instead of using the approximate pseudopotential of the infinite disk geometry in the previous study 18, we construct an exact form of the pseudopotential based on the relativistic Landau model recently analyzed by one of the authors 19. Previous numerical studies on fractional quantum Hall states in graphene show the existence of a Laughlin state at $\nu = 1/3$ even in the $n = 1$ Landau level 20,21 where the charge excitation gap is larger than that of the $n = 0$ Landau level. This stability of the Laughlin state in the $n = 1$ Landau level is a unique feature of the linear dispersion of the Dirac

FIG. 1. Schematic of the energy spectrum and Landau level. (a) and (b) show the massless and the massive cases ($M > 0$), respectively. ($g$ represents a monopole charge.) The right figure of (b) shows asymmetry between the positive and negative energy levels due to the absence of $-M$. (In general, there exists the energy level $E = +\text{sgn}(g \cdot M) |M|$ while not $E = -\text{sgn}(g \cdot M) |M|$.) The original reflection symmetry of the energy levels with respect to the zero-energy is broken due to the mass term.
equation. We study how this stability of the Laughlin states changes with increase of mass. Based on the exact diagonalization, we numerically obtain a many-body ground state of the relativistic pseudopotential Hamiltonian, and analyze the mass effect to the Laughlin state at $\nu = 1/3$ in the $n = 1$ relativistic Landau level.

II. RELATIVISTIC LANDAU PROBLEM ON A SPHERE

In this section, we give a brief review of the relativistic Landau problem on the Haldane’s sphere and discuss its mass deformation. The monopole gauge field is given by

$$A = -g \cos \theta \, d\phi,$$  \hspace{1cm} (2.1)

where $g$ denotes the monopole charge. (In the following, we assume that $g$ is positive for simplicity.) The Dirac operator on the Haldane sphere can be represented as

$$-i\mathcal{D} = -i\epsilon_{\mu}^{\nu} \gamma^{\mu} (\partial_{\mu} + i\omega_{\mu} - i A_{\mu}),$$

where $\epsilon_{\mu}^{\nu} (m = 1, 2, \mu = \theta, \phi)$ denote the two-bein of two-sphere whose non-zero components are $\epsilon_1^\theta = 1/R$, $\epsilon_2^\phi = 1/(R \sin \theta)$ ($R$ is the radius of the Haldane sphere) and $\omega_{\mu}$ stands for the spin connection. When we adopt the 2D gamma matrices as $(\gamma^1, \gamma^2) = (\sigma_x, \sigma_y)$, the spin connection is expressed as $\omega_\theta = 0, \omega_\phi = \frac{1}{2} \sigma_z$, and then the Dirac operator takes the form of

$$-i\mathcal{D} = -i\frac{1}{R} \sigma_x \partial_\theta - i\frac{1}{R \sin \theta} \sigma_y (\partial_\theta + i(g - \frac{1}{2} \sigma_z) \cos \theta)
= -i\frac{1}{R} \sigma_x (\partial_\theta + \frac{1}{2} \cot \theta) - i\sigma_y \frac{1}{R \sin \theta} (\partial_\theta + ig \cos \theta),$$  \hspace{1cm} (2.2)

or

$$-i\mathcal{D} = \frac{1}{R} \begin{pmatrix} 0 & -ig \cos \theta + \frac{1}{2} \sigma_z \\ -ig \cos \theta - \frac{1}{2} \sigma_z & 0 \end{pmatrix}. $$  \hspace{1cm} (2.3)

Here $\partial_{\theta}^{(g+\frac{1}{2})}$ are the edth operators:

$$\partial_{\theta}^{(g+\frac{1}{2})} = \partial_\theta + ig \cot \theta \pm \frac{1}{2} \ln \theta \, \partial_\phi. $$  \hspace{1cm} (2.4)

For graphene, two components of the Dirac spinor indicate sublattice degrees of freedom, while for a topological insulator the real spin degrees of freedom of surface electron. The eigenvalues of the Dirac operator (2.2) are derived as

$$\pm \lambda_n = \pm \frac{1}{R} \sqrt{n(n+2g)}, \quad (n = 0, 1, 2, \cdots) $$  \hspace{1cm} (2.5)

where $n$ corresponds to the relativistic Landau level index. Notice that the spectrum (2.5) exhibits the reflection symmetry with respect to the zero energy. Each Landau level $\pm \lambda_n$ accommodates the following degeneracy

$$d_{\lambda_n} = d_{-\lambda_n} = 2(g+n). $$  \hspace{1cm} (2.6)

The degenerate eigenstates of the Landau level are

$$\psi_{\pm \lambda_n, m}^g (\theta, \phi) = \frac{1}{\sqrt{2}} \begin{pmatrix} Y_{j=g-(\frac{1}{2}+n),m}^\theta (\theta, \phi) \\ \mp Y_{j=g-(\frac{1}{2}+n),m}^\phi (\theta, \phi) \end{pmatrix}, $$

$$n = 0: \psi_{0,0}^g (\theta, \phi) = \begin{pmatrix} Y_{g-\frac{1}{2},\frac{1}{2}}^\theta (\theta, \phi) \\ 0 \end{pmatrix}, $$

with $m = -g + \frac{1}{2} + n, -g + \frac{1}{2} + n, \cdots, g - \frac{1}{2} + n$. $Y_{j,m}^g$ denote the monopole harmonics [22].

$$Y_{l,m}^g (\theta, \phi) = 2^m \sqrt{\frac{(2l+1)(l-m)!(l+m)!}{4\pi(l-g)!(l+g)!}} \times (1-x)^{-\frac{m+1}{2}} (1+x)^{-\frac{m+1}{2}} P_l^{m-m-g} (x) \cdot e^{im\phi}, $$  \hspace{1cm} (2.8)

where $x = \cos \theta$ and $P_n^{(\alpha,\beta)} (x)$ stand for the Jacobi polynomials.

The magnetic field does not affect the spectrum symmetry between the positive and negative Landau levels [25], but acts unevenly on the upper and lower components of the eigenstates, which can most apparently be seen from the absence of the lower component of the zero-mode (2.7b). Also notice that the components of the eigenstates, which can most apparently accommodate the following degeneracy (2.6), 2

$$[J_z, -i\mathcal{D}] = 0, $$  \hspace{1cm} (2.12)

and so there exist the simultaneous eigenstates (2.7) of the Dirac operator and the $SU(2)$ Casimir. Each relativistic Landau level thus accommodates the $SU(2)$ degeneracy (2.6), $2j+1 = 2(g+n)$.

The Dirac operator also respects the chiral symmetry,
\[ \{-i\slashed{D}, \sigma_z\} = 0, \quad (2.13) \]
and the spectrum of the Dirac operator is symmetric with respect to the zero eigenvalue \( \Lambda \). The non-zero Landau level eigenstates of the same eigenvalue magnitude \( \Lambda \) are related by the chiral transformation:
\[ \psi^{g}_{\pm \Lambda_n, m} = \sigma_z \psi^{g}_{\mp \Lambda_n, m}. \quad (2.14) \]

A. Mass deformation

We apply a mass deformation to the Dirac operator:
\[ -i\slashed{D} + \sigma_z M = \frac{1}{R} \left( \begin{array}{cc} RM & -i\delta^{(g+1)} \sigma_z \\ -i\delta^{(g+1)} & -RM \end{array} \right). \quad (2.15) \]
The mass deformation does not break the \( SU(2) \) rotational symmetry of the system
\[ [\sigma_z M, J_z] = 0, \quad (2.16) \]
but break the chiral symmetry, \( \{\sigma_z M, \sigma_z\} = 2M \neq 0 \). The mass deformation is expected to bring asymmetry between the positive and negative spectrum. The \( m \)-th mass deformed Dirac operator yields
\[ (-i\slashed{D} + \sigma_z M)^2 = (-i\slashed{D})^2 + M^2, \quad (2.17) \]
and the eigenvalues of the mass deformed Dirac operator are obtained as
\[ n = 1, 2, \cdots : \pm \Lambda_n = \frac{1}{R} \sqrt{n(n+2g)+(MR)^2}, \quad (2.18a) \]
\[ n = 0 : \Lambda_0 = +M. \quad (2.18b) \]

Note that for \( n \geq 1 \) the spectra \( (2.18a) \) still respect the reflection symmetry with respect to the zero energy, while \( n = 0 \) \( (2.18b) \) does not have its counterpart of the negative energy \( -M \) [Fig. 2]. This asymmetry is a manifestation of the “parity anomaly” as mentioned in Introduction. The corresponding eigenstates for \( (2.18) \) are respectively given by
\[ n = 1, 2, \cdots : \psi^{g}_{\pm \Lambda_n, m} = \sqrt{\frac{\Lambda_n + \frac{\Lambda_0}{2\Lambda_n}}{2\Lambda_n}} \left( \psi^{g}_{\pm \Lambda_n, m} \pm \frac{M}{\Lambda_n + \frac{\Lambda_0}{2\Lambda_n}} \psi^{g}_{\mp \Lambda_n, m} \right), \quad (2.19a) \]
\[ n = 0 : \psi^{g}_{\Lambda_0 = M, m} = \psi^{g}_{\Lambda_0 = 0, m}, \quad (2.19b) \]
where \( m = -n-g+\frac{1}{2}, -n-g+\frac{3}{2}, \cdots, n+g-\frac{1}{2} \). One may find that \( \psi^{g}_{\Lambda_0 = M, m} \) \( (2.19b) \) are simply the zero-modes of the massless Dirac operator, while \( \psi^{g}_{\pm \Lambda_n, m} \) and \( \psi^{g}_{-\Lambda_n, m} \) \( (2.19a) \) are linear combinations of the chirality partners of non-zero Landau levels, \( \psi^{g}_{\pm \Lambda_n, m} \) and \( \psi^{g}_{-\Lambda_n, m} \), and reduced to them in \( M \to 0 \). The mass deformation is inert to the Landau level degeneracy; each of the Landau levels \( \pm \Lambda_n \) has the same degeneracy \( 2d_{\pm \Lambda_n} = 2(g+n) \), since the \( SU(2) \) symmetry is kept exact even under the mass deformation.

Meanwhile in \( M \to \infty \) which we call the non-relativistic limit, the positive Landau level spectra \( (2.18a) \) are reduced to
\[ +\Lambda_n \simeq M + \frac{1}{2MR^2} n(n+2g) + O\left( \frac{1}{M^3} \right), \quad (2.20) \]
and the eigenstates \( (2.19a) \) are
\[ \psi^{g}_{\pm \Lambda_n, m} \simeq \frac{1}{\lambda^2} \left( \psi^{g}_{\pm \Lambda_n, m} + \psi^{g}_{-\Lambda_n, m} \right) = \left( \begin{array}{c} \psi^{g}_{\pm \Lambda_n, m} + \psi^{g}_{-\Lambda_n, m} \\ 0 \end{array} \right). \quad (2.21) \]

Notice that the next leading order term on the right-hand side of \( (2.20) \) is equal to the non-relativistic Landau levels \( \left[ 17 \right] : \)
\[ E_n = \frac{1}{2MR^2} n(n+2g+1)+g, \quad (2.22) \]
with replacement from \( (n, g) \) to \( (n, g - \frac{1}{2}) \) up to a unimportant constant and for the eigenstates \( (2.21) \) also. Thus in the non-relativistic limit, \( n \)th positive relativistic Landau level is reduced to \( n \)th non-relativistic Landau level with monopole charge \( g - \frac{1}{2} \). Similarly for the negative relativistic Landau level, we have
\[ -\Lambda_n \simeq -M - \frac{1}{2MR^2} n(n+2g) + O\left( \frac{1}{M^3} \right), \quad (2.23) \]
\[ \psi_{j,m}^g \simeq \frac{1}{\sqrt{2}} (\psi_{j,m}^g - \psi_{j,m}^g) = i \left( Y_{j+\frac{1}{2}}^g \psi_{j+\frac{1}{2}+n-1,m}^g \right). \]

The next leading order term of the opposite sign on the right-hand side of (2.23) is equal to the non-relativistic Landau level (2.22) with replacement from \((n, g)\) to \((n - 1, g + \frac{1}{2})\) and for the eigenstates (2.23) also. Thus in the non-relativistic limit, up to a constant, (the absolute value of) the \(n\)th negative relativistic Landau level reproduces \((n - 1)\)th non-relativistic Landau level with monopole charge \(g + \frac{1}{2}\).

To summarize, the mass parameter interpolates the \(n\)th positive/negative relativistic Landau level physics \((M \to 0)\) and the \(n/n - 1\)th non-relativistic Landau level physics \((M \to \infty)\). It is important to note that the positive and negative relativistic Landau levels approach to the different non-relativistic Landau levels in the \(M \to \infty\) limit. We will revisit this in the context of many-body physics in Sec. IV.

### III. RELATIVISTIC PSEUDOPOTENTIAL

We next construct a relativistic pseudopotential on the Haldane sphere. Neglecting Landau level mixing, the projection Hamiltonian onto the \(n\)th Landau level is given by

\[ H = \sum_{p < q} \sum_{J} V_{pq}^J \mathcal{P}_J(p, q) \]

where \(V_{pq}^J\) is Haldane’s pseudopotential in \(n\)th Landau level and \(\mathcal{P}_J(p, q)\) projects onto states in which \(p\)th and \(q\)th particles have two-body angular momentum \(J\). \(\mathcal{P}_J(p, q)\) is given by

\[ \mathcal{P}_J(p, q) = \prod_{J' \neq J} \left( \frac{J_p + J_q}{J(J+1) - J'(J'+1)} \right) \]

where \(J_p\) represents the angular momentum operator for the \(p\)th particle and \(J(J+1)\) is the eigenvalue of \((J_p + J_q)^2\). Due to the Wigner-Eckart theorem, the pseudopotential can be expressed as

\[ V_{pq}^J \delta_{J,J'} = \langle J, J' | V | J, J' \rangle \]

where \(V \) is Coulomb interaction and \(| J, J' \rangle\) denotes a two-particle state with azimuthal angular momentum \(J\).

Let us begin with the massless case. For notational brevity, we rewrite the relativistic eigenstates (2.25) as the state vector \(| j, m, g \rangle\):

\[ | j, m, g \rangle_{\pm \lambda_n} = \frac{1}{\sqrt{2}} (| j, m, g + \frac{1}{2} \rangle \mp i | j, m, g - \frac{1}{2} \rangle) \]

(3.4)
Next we move to the massive case. The relativistic eigenstate \( |j, m, g, M\rangle \) can be rewritten as
\[
|j, m, g, M\rangle_{\pm\Lambda_n} = \frac{1}{2}\sqrt{\frac{\Lambda_n + \lambda_n}{\Lambda_n}} \times \left[ (1 \pm \frac{M}{\Lambda_n + \lambda_n}) |j, m, g - \frac{1}{2}| \uparrow \right. \\
\left. \mp i(1 \mp \frac{M}{\Lambda_n + \lambda_n}) |j, m, g + \frac{1}{2}| \downarrow \right],
\]
and in a similar manner to the massless case, the pseudopotentials are derived as
\[
V^R_m(M)_{\pm\Lambda_n} = \frac{1}{4}\left( (1 \pm \frac{M}{\Lambda_n})^2 V_j(j, g - \frac{1}{2}, g - \frac{1}{2}) \\
+ (\frac{\lambda_n}{\Lambda_n})^2 (V_j(j, g - \frac{1}{2}, g + \frac{1}{2}) + V_j(j, g + \frac{1}{2}, g - \frac{1}{2})) \\
+ (1 \mp \frac{M}{\Lambda_n})^2 V_j(j, g + \frac{1}{2}, g - \frac{1}{2}) \right].
\]

It is easy to confirm that (3.12) is reduced to (3.9) in the massless limit \( M \to 0 \). Superficially the mass gap might not seem to have something to do with the Coulomb interaction, but quite interestingly the mass gap indeed alters the strength of the effective Coulomb pseudopotential as found in (3.12). Since the \( SU(2) \) generators are immune to the mass deformation, the mass deformation affects the projection Hamiltonian (3.1) not through the projection operators (3.2) but through the pseudopotentials (3.12) only.

In the following discussions, we express the pseudopotentials as a function of the relative angular momentum \( m = 2j - J \). The readers should notice that \( V_m \) in the following sections indicates \( V_{j=2j-m} \) used in this section.

**IV. NUMERICAL RESULTS**

To investigate the physics of the mass deformation on many-body states, we perform an exact diagonalization study at \( \nu = 1/3 \). We focus on the single Dirac Hamiltonian, which describes the surface electrons of a 3D topological insulator or graphene with full spin and valley polarization. In the following, we set \( e^2/\epsilon B \) to unity. (\( \epsilon \) is a dielectric constant.) It is well known that the ground state is described by the Laughlin state at \( \nu = 1/q \) (\( q \) is odd integer) (22). In the spherical geometry, the Laughlin state is realized when the total flux \( N_\Phi \) is given by (17, 26)
\[
N_\Phi = 2j = \nu^{-1}(N_e - 1)
\]
where \( N_e \) is the number of electrons in a partially filled Landau level. We define the total energy as
\[
E(N_\Phi) = E_C(N_\Phi) - \frac{N_e^2}{2R}
\]
where the first term represents the energy of Coulomb interaction and the second term means the effect of the neutralizing background and the self-energy of the background.

We also assess the energy gap for the creation of a quasiparticle or a quasihole as
\[
\Delta_\pm = E(N_\Phi \pm 1) - E(N_\Phi)
\]
where \(+/-\) indicates to quasihole/quasiparticle. A thermal excitation is a neutral pair of a quasiparticle and a quasihole whose excitation gap is given by
\[
\Delta_e = \Delta_+ + \Delta_-
\]
for infinite separation.

**A. Massless case**

We first investigate the massless relativistic case for comparison to the non-relativistic results obtained by...
effect of the sphere will vanish in $R$ fixed and disk geometry [28]:

\[ g \text{ and filled circles represent the lowest energies in unit of } e^2/\epsilon B \text{ and } e^2/\epsilon_B \text{, respectively. The solid (dotted) line shows the linear (square) fitting for each of the energies.} \]

(b) Overlaps with Laguerre polynomials $L_n$. (d) respectively show the charge gap and the rescaled one at $n = 1$ Landau level and the Laughlin wave function. (c) and (d) respectively show the charge gap and the rescaled one at $n = 1$ Landau level and the Laughlin wave function.

The charge gap of the Laughlin state strongly depends on $V_1 - V_0$ [26], we focus on $V_1 - V_3$. In Fig. 3(b) we compare the $m$-dependence of the pseudopotentials between the relativistic $V_{m}^{R}$ in $n = 1$ and the non-relativistic $V_{m}^{N R} = V_j(j, g, g)_{j=n+g}$ in $n = 0$ and 1. The value of $V_1 - V_0$ of non-relativistic $n = 1$ Landau level is the smallest, and hence its Laughlin state is considered to be unstable against large thermal and impurity effects in the energy unit of $e^2/\epsilon_B$ in the experimental situation. (Also notice that the pseudopotential shows a cusp at the relative angular momentum $m = 2$.) Meanwhile, the $n = 1$ relativistic pseudopotential $V_{m}^{R}$ shows a monotonic decay as a function of the relative angular momentum and its $V_{m}^{R} = 1$ is the largest. Therefore, the Laughlin state in the $n = 1$ relativistic level is expected to be more stable than those of the non-relativistic levels $n = 0, 1$ [18, 21].

To obtain the properties of the bulk limit, we need the extrapolation on the size of systems. We, however, sometimes have strong finite-size effects (for example, see the open circles in Fig. 3(a)). Fortunately, with the rescaled magnetic length $l_B = \sqrt{N_e/\epsilon B} = \sqrt{(N_e - 1)/\epsilon B}$, the state energy and the charge gap in units of $e^2/\epsilon_B$ give us good extrapolated values even if the number of electrons is small [30]. Indeed, the open circles in Fig. 3(a) showing the lowest energies for each $N_e$ in the unit of $e^2/\epsilon_B$ have large size dependence compared with that of the filled circles in Fig. 3(a), which correspond to the energies rescaled by $l_B$. The filled circles are scaled by a linear function to have $E_0(N_e \to \infty) \approx -0.3721$.

Figure 4(b) exhibits the overlaps $\langle \Psi_0 | \Psi_L \rangle$ between the numerical ground state $| \Psi_0 \rangle$ at $\nu = 1/3$ of the relativistic $n = 1$ Landau level and the Laughlin wave function $| \Psi_L \rangle$. The Laughlin state has a remarkably large overlap $\langle \Psi_0 | \Psi_L \rangle$ for each $N_e$ more than 99%, which strongly suggests that the many-body groundstate of the relativistic $n = 1$ Landau level is the Laughlin state.

Figure 4(c) displays the charge gap $\Delta_e$ [41] at $\nu = 1/3$ of the relativistic $n = 1$ and non-relativistic $n = 0$ Landau levels, and Fig. 4(d) exhibits the rescaled charge gap $\Delta_e^{\text{rescaled}}$. The charge gap in the relativistic $n = 1$ Landau level is larger than that in the non-relativistic $n = 0$ Landau level. This is expected from the previous observation that the Laughlin state in the relativistic Landau level is more stable than in the non-relativistic Landau level. From the rescaled charge gap, we obtain $\Delta_e \approx 0.1163$ in the relativistic $n = 1$ Landau level. This value is in agreement with previous work using $V_{m}^{\text{Disk}}$ in larger systems [18].

**B. Massive case**

We investigate the mass effect on the $n = 1$ positive and negative relativistic Landau levels. In particular, we discuss the mass dependent behavior of the Laughlin state of $n = 1$, which is the many-body groundstate in the massless case. Figures 4(a) and 4(b) show the mass de-
dependence of the pseudopotentials. To express the mass dependence of quantities, we adopt a dimensionless mass parameter, $M/\lambda_n$ with $\lambda_n = \frac{m}{2}\nu$ being the kinetic energy of the $n = 1$ relativistic Landau level. As shown in Fig. 5(a), for the negative relativistic Landau level $-\Lambda_{n=1}$, its behavior is similar to that of the massless case in Fig. 3(a), while with the increase of $M/\lambda_n$, the pseudopotential shows a cusp at $m = 2$, which is a unique feature of the $n = 1$ non-relativistic pseudopotential as depicted in Fig. 5(b). We thus have derived a concrete behavior of the pseudopotentials with respect to the mass parameter and demonstrated that the mass parameter interpolates the relativistic pseudo-potential ($M \to 0$) and non-relativistic one ($M \to \infty$).

Since the pseudo-potential Hamiltonian dominates the many-body physics in a given Landau level, it may be natural to expect that the mass parameter also interpolates the relativistic and non-relativistic many-body physics. The overlap $\langle \Psi_0 |\Psi_f \rangle$ at $\nu = 1/3$ in $N_e = 7, 8$ and $9$ systems as a function of $M/\lambda_n$ is shown in Fig. 6(a). The overlap in the negative relativistic Landau level $-\Lambda_{n=1}$ keeps large values more than 99% all over $M/\lambda_n = 1$ (left-figure). Meanwhile, the overlap in the relativistic positive Landau level $+\Lambda_{n=1}$ rapidly decreases with increasing $M/\lambda_n = 1$ (right-figure) and finally reduces to about 50% in a $N_e = 9$ system in the large $M/\lambda_n = 1$ region. Besides, the overlap becomes strongly suppressed with the increase of $N_e$ [Fig. 6(a)]. Hence in the thermodynamic limit, the overlap will be significantly reduced even if the mass is not so large. The charge gap in the thermodynamic limit ($N_e \to \infty$) can be obtained from the rescaled charge gap $\Delta_c^{\text{rescaled}}$ as deduced at $1/N_e \to 0$ in Fig. 6(d). The charge gap $\Delta_c^{\text{rescaled}}$ ($N_e \to \infty$) also exhibits a rapid decay in $+\Lambda_{n=1}$ as shown in Fig. 6(b). Thus the Laughlin state is no longer a good candidate for the ground state with large $M/\lambda_n = 1$ in $+\Lambda_n$, and in the $M \to \infty$ limit the groundstate will become to that of the non-relativistic $n = 1$ Landau level.

Let us consider these results in view of the parity anomaly. In the massless case, the relativistic system respects the chiral symmetry and so the pseudopotentials in the positive and negative relativistic Landau levels are equivalent. When $M$ is turned on, accompanied with the chiral symmetry breaking, the mass deformed pseudopotential becomes non-

dopotentials in ±Λν begin to split according to \[6.12\]. Since in the non-relativistic limit (\(M \to \infty\)), \(\psi_{+\Lambdaν}\) and \(\psi_{-\Lambdaν}\) are reduced to the non-relativistic eigenstates in \(\nu\)th and \((n - 1)\)th Landau levels [remember the discussions in Sect.1A], \(V^R_j(M)_{+\Lambdaν}\) and \(V^R_j(M)_{-\Lambdaν}\) are also reduced to the non-relativistic pseudopotentials of the \(n\) and \((n - 1)\)th Landau levels respectively. As a result, while the ground state in \(-\Lambdaν=1\) keeps being characterized by the Laughlin state, in \(+\Lambdaν=1\) the groundstate is no longer given by the Laughlin state in the large \(M\) region. Thus, the “parity anomaly” brings inequivalence also to the many-body physics of the relativistic quantum Hall effect.

V. SUMMARY AND DISCUSSIONS

We developed a relativistic formulation of the quantum Hall effect on the Haldane sphere and performed numerical investigations. Specifically, we analyzed the properties of the relativistic quantum Hall liquid at \(\nu = 1/3\) by the exact diagonalization based on the newly constructed relativistic pseudopotential Hamiltonian. Though in the massless case either of relativistic many-body groundstates for the \(n = 1\) positive and negative relativistic Landau levels are well described by the Laughlin wavefunction, our numerical results indicate that the mass term significantly reduces the charge gap of the positive relativistic Landau level \(n = 1\) and the Laughlin state no longer well describes the many-body groundstate in the presence of a sufficiently large mass. Since the mass-dependent behaviors are enhanced with the increase of the number of electrons, our results will maintain correct in the thermodynamic limit even if the mass gap is not so large.

Here, we note the energy scale of the mass term in experimental Dirac matter. For graphene and topological insulators (such as Bi2Se3), the Fermi velocity \(v_F\) is in the order of \(1\times10^6\) \(\text{m/s}\) and \(1\times10^5\) \(\text{m/s}\), respectively. The level spacing between the relativistic \(n = 0\) and \(n = 1\) Landau levels is given by \(\sqrt{2}\hbar v_F/\ell_B \approx 4\sqrt{B[T]} \times 10^{-5}\) meV. Meanwhile, the mass gap induced by the breaking of the AB sublattice symmetry of graphene is reported as 260 meV \[11\], and that of the Bi2Se3 topological insulator surface with 16% Fe doping is estimated about 50 meV \[13\]. Thus, for both graphene and topological insulator surfaces, the mass parameter can become comparable with (or even larger than) the Landau level spacing by controlling an external magnetic field. It is expected that the present results will be observable in real Dirac matter.

NOTE ADDED IN PROOF

While revising the paper, we were aware of a work by Arciniaga and Peterson \[34\] in which they independently explored a relativistic formulation of the quantum Hall effect on the Haldane sphere.

ACKNOWLEDGMENTS

KH would like to thank Hiroaki Matsueda for arranging a seminar at Tohoku University which enabled the present collaboration. This work was supported by JSPS KAKENHI Grant No. 26400344, No. 16K05334, and No. 16K05138.

Appendix A: Derivation of the pseudopotential

We derive an explicit representation of \(V^R_j\) \[39\] using the method of Ref. \[25\]. From the definition of the pseudopotential and the two-particle state, \(V(j, \alpha, \beta)\) in the main text is given by

\[
V_j(j, \alpha, \beta) = \sum_{m_1, m_2, n_1, n_2} C^{J_1 L_1}_{j m_1, j m_2} C^{J_2 L_2}_{j m_1, j m_2} \langle j, m_1, \alpha; j, m_2, \beta | V(j, n_1, \alpha; j, n_2, \beta) \rangle. \quad (A.1)
\]

Here, \(V\) is the Coulomb interaction on the sphere, \(V(r_1 - r_2) = e^2/\epsilon \epsilon_0 |r_1 - r_2|\) with \(|r_1| = |r_2| = R\), which can be expressed as

\[
V(r_1 - r_2) = e^2 \sum_{k=0}^{\infty} \frac{4\pi}{2k+1} \sum_{m'=-k}^{k} Y_{k, m'}^*(\Omega_1) Y_{k, m'}(\Omega_2), \quad (A.2)
\]

where \(Y_{k, m'}\) are spherical harmonics and \(\Omega_p\) means the spherical coordinate \((\theta_p, \phi_p)\) for the \(p\)th particle. The matrix elements of \((A.1)\) are written as

\[
\langle j, m_1, \alpha; j, m_2, \beta | V(j, n_1, \alpha; j, n_2, \beta) \rangle = \sum_{k=0}^{\infty} \frac{4\pi}{2k+1} \times \int Y_{j, m_1}^\alpha (\Omega_1)^* Y_{k, m'}^*(\Omega_1) d\Omega_1 \times \int Y_{j, m_2}^\beta (\Omega_2) Y_{k, m'}^*(\Omega_2) d\Omega_2. \quad (A.3)
\]

Using properties of the monopole harmonics \[22, 23\],

\[
Y_{k, m'}(\Omega) = Y_{0, m'}^0(\Omega), \quad (A.4a)
\]

\[
Y_{j, m}^g(\Omega)^* = (-1)^{g+m} Y_{j, -m}^{-g}(\Omega), \quad (A.4b)
\]

\[
\int Y_{j, m}^g(\Omega) Y_{k, m'}^0(\Omega) Y_{j, n}^{g'}(\Omega) d\Omega = (-1)^{2j+k} \times \left[ \frac{(2j+1)(2k+1)(2j'+1)}{4\pi} \right]^{1/2} \begin{pmatrix} j & k & j' \\ g & 0 & g' \end{pmatrix} \begin{pmatrix} j & k & j \\ m & m' & n \end{pmatrix}, \quad (A.4c)
\]
we can represent \( [A.3] \) as

\[
\langle j,m_1, \alpha; j,m_2, \beta | V | j,n_1, \alpha; j,n_2, \beta \rangle =
\]

\[
\frac{e^2}{cR} \sum_{k=0}^{2j} \sum_{m=-k}^{k} (2j+1)^2 \left( \begin{array}{ccc} j & k & j \\ -\alpha & 0 & 0 \end{array} \right) \left( \begin{array}{ccc} j & k & j \\ -\beta & 0 & 0 \end{array} \right) \times \left( \begin{array}{ccc} j & k & j \\ -m_1 & m'_{n_1} \end{array} \right) \left( \begin{array}{ccc} j & k & j \\ -m_2 & m'_{n_2} \end{array} \right).
\]

(A.5)

Note that \( \sum_{k=0}^{\infty} \) reduces a finite sum up to \( 2j \) since the \( 3j \)-symbol is finite for \( 0 \leq k \leq 2j \). Since \( V_{ij}(j, \alpha, \beta) \) does not depend on \( J_z \), the sum on the right-hand side of \( [A.1] \) can be rewritten as

\[
\sum_{m_1,m_2,n_1,n_2,m',J_z} (\ldots) = \frac{1}{2J+1} \sum_{m_1,m_2,n_1,n_2,m',J_z} (\ldots).
\]

(A.6)

With \( [A.7] \) and the definition of the \( 6j \)-symbol

\[
\left\{ \begin{array}{c} j_1 \, j_2 \, j_3 \\ j_4 \, j_5 \, j_6 \end{array} \right\} \equiv \sum_{\{m_i\}} (-1)^{\Delta} \left( \begin{array}{ccc} j_1 & m_1 & j_6 \\ -m_3 & m_4 & j_2 \\ -m_5 & m_5 & j_3 \end{array} \right)
\]

(A.7)

we can perform the summation over \( m_1,m_2,n_1,n_2,m',J_z \) in \( [A.1] \) to obtain \( [3.10] \).
