Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
COVID-19-related organ dysfunction and management strategies on the intensive care unit: a narrative review

Summary

The coronavirus disease 2019 (COVID-19) pandemic has resulted in a significant surge of critically ill patients and an unprecedented demand on intensive care services. The rapidly evolving understanding of pathogenesis, limited disease specific evidence, and demand-resource imbalances have posed significant challenges for intensive care clinicians. COVID-19 is a complex multisystem inflammatory vasculopathy with a significant mortality implication for those admitted to intensive care. Institutional strategic preparation and meticulous intensive care support are essential to maximising outcomes during the pandemic. The significant mortality variation observed between institutions and internationally, despite a single aetiology and uniform presentation, highlights the potential influence of management strategies on outcome. Given that optimal organ support and adjunctive therapies for COVID-19 have not yet been well defined by trial-based outcomes, strategies are predicated on existing literature and experiential learning. This review outlines the relevant pathophysiology and management strategies for critically ill patients with COVID-19, and shares some of the collective learning accumulated in a high volume severe respiratory failure centre in London.

Keywords: ARDS; COVID-19; ECMO; MODS; respiratory failure; SARS-CoV-2; ventilation

Severe acute respiratory distress syndrome coronavirus 2 (SARS-CoV-2) is a novel enveloped RNA beta-coronavirus associated with coronavirus disease 2019 (COVID-19).1 The viral genomic sequence and clinical significance was outlined by the WHO on January 12 2020, and has since been declared a global pandemic.2 The first case in the UK was confirmed on the January 31, 2020, and by the end of June, there had been 312 654 confirmed cases and 43 730 deaths.3 Guy’s and St. Thomas’ NHS Foundation Trust is one of six severe respiratory failure (SRF) centres in the UK, and offers a complete spectrum of advanced respiratory support including extracorporeal membrane oxygenation (ECMO). By virtue of its central London location and SRF referral network covering a population of 18 million people, the critical care department has admitted 329 patients with COVID-19 to date, including 58 mobile ECMO retrievals. This has facilitated a rapid learning of...
disease behaviour and emerging phenotypes, and allowed tailored patient therapies to evolve accordingly. Despite a significant surge of patients, the authors have been encouraged by their 71.1% survival to critical care discharge, which compares favourably to large contemporaneous datasets in the UK and Italy. This narrative review looks at the relevant pathophysiology and management strategies for critically ill COVID-19 patients, and shares some of the collective learning accrued in a quaternary SRF centre.

History and presentation

The majority of early SARS-CoV-2 infections were related to zoonotic exposure in Huanan Seafood Wholesale Market in Wuhan, China; however, human-to-human transmission has since been demonstrated in the initial outbreak. Although respiratory tract related droplets likely account for the majority of new infections, there is increasing interest in the potential for fomite, aerosol, and faeco-oral transmission. These factors, combined with a large proportion of infectious patients with only mild or asymptomatic carriage, makes pertinent contact and travel history insensitive tools for stratifying the risk of COVID-19.

Beta-coronaviruses enter the body predominantly through the angiotensin converting enzyme-2 (ACE2) receptors, and this is followed by intracellular translocation. The abundance of ACE2 receptors within the lower respiratory tract explains the high incidence of cough (67.8%) amongst symptomatic cases at presentation. COVID-19 may also be associated with pyrexia (43.8%), fatigue (38.1%), anosmia (19.4%), myalgia (14.9%), sore throat (13.9%), headache (13.6%), and diarrhea (3.8%). Disease severity can be highly variable ranging from asymptomatic through to fulminant multiorgan failure. These variations may be related to the route of transmission, inoculation dose, and host immunity status.

The median (inter-quartile range [IQR]) incubation period, time from first symptoms to hospital admission, and first symptoms to developing acute respiratory distress syndrome (ARDS) are 4 days (IQR, 2–7), 7 days (IQR, 4–8), and 8 days (IQR, 6–12), respectively. To date, the 10 624 patients requiring critical care in the UK have been predominantly male (70.2%) with a median age of 60 (IQR, 51–68) yr and an increased BMI > 25 kg m$^{-2}$ (73.7%). Critically ill patients are also more likely to have a smoking history and underlying cardiovascular comorbidities.

Given the variability in host response during different stages of COVID-19, the authors have found it helpful to conceptualise three phases of illness after an incubation period (Fig. 1). Although these phases represent a continuum of disease, the varied behaviour observed in certain phases may lend themselves to time-sensitive tailored therapies:

1. Phase one (0–7 days after symptoms develop): rapid viral replication and innate immune response phase resulting in the symptomology outlined, lymphopenia, and elevated inflammatory biomarkers and cytokine concentrations. In this early phase, focal peri-bronchovascular and subpleural ground glass opacities on CT can precede respiratory symptoms.

2. Phase two (5–14 days after symptoms develop): organ dysfunction phase related to ongoing viral cytopathic and emerging adaptive immune response. Two
Divergent groups appear to develop with an acute respiratory failure necessitating early invasive ventilatory support and those with more indolent organ dysfunction.15

3. Phase three (>10 days after symptoms develop): this late deterioration despite invasive organ support is mediated by either:

• Hyperinflammation: dysregulated immune response appears to take the form of either a persistent systemic hyperinflammatory state, a more limited pulmonary hyperinflammation or rarely idiosyncratic hyperinflammatory syndromes such as secondary haemophagocytic lymphohistiocytosis (sHLH) or cytokine release syndrome (CRS).17

• Organ support complications: the severe pulmonary inflammation observed in COVID-19 appears to be exquisitely sensitive to the myriad of complications of critical illness and organ support; including patient self-inflicted lung injury, ventilator-induced lung injury, extravascular lung water (EVLW) accumulation, nosocomial infections, and multiorgan dysfunction syndrome.18–20

**Respiratory system**

Despite profound hypoxaemic respiratory failure being the dominating clinical feature of COVID-19, a unifying explanation of the pathophysiology remains contentious.1,12 Beta-coronaviruses usually enter the body through the binding of surface spike glycoprotein via the variable receptor-binding protein (mutated RaTG13) to the ACE2 receptors, and this is followed by intracellular translocation of virions through endocytosis or direct cell membrane fusion.10 ACE2 receptors are expressed principally on type II pneumocytes but can also be found within the kidney, enterocytes, and cardiac myocytes.16,13 SARS-CoV-2 can elicit a pronounced inflammatory response through antigen presenting cells, and induction of cytokines and chemokines.15 It remains uncertain what proportion of the pneumonitis and increased vascular permeability is driven by the viral cytopathy or dysregulated immune response.

The hypoxaemia seen in the early stages of COVID-19 has a different pathophysiology to that described in typical ARDS. Type-L phenotype presents with focal subpleural and peripheral ground glass opacifications, limited atelectasis, low EVLW, and low elastance, and the main mechanism seems to be ascribed to a dysregulation of pulmonary perfusion.22 Recent histological data suggest an early isolated lymphocytic viral pneumonia in COVID-19 with later transition to an acute fibrinous and organising pneumonia.23 Whilst the validity of such respiratory phenotypes in COVID-19 has been widely debated, it is important to remember that ARDS has never been a distinct diagnosis but rather a syndrome with a number of subphenotypes and different aetiologies.24 This syndrome represents a final common pathway for a hugely heterogenous group of diseases that may require biologically targeted therapies in addition to lung protective ventilation (LPV).

These focal ground glass opacifications observed in early disease cannot fully explain the significant shunt fraction often observed. The aetiology of this early respiratory failure and disproportionate hypoxaemia is likely multifactorial:

• Pulmonary vasculopathy with loss of adaptive hypoxic pulmonary vasoconstriction and dysregulated pulmonary perfusion.21,22 Although the pivotal role ACE2 receptors play in SARS-CoV-2 transmission is well defined, their expression within the pulmonary endothelium and role in dysregulated pulmonary perfusion is now becoming apparent.21 The carboxypeptidase ACE2

**Table**

| Phenotype | Chest radiograph | CT | Low flow PV curve | Gas exchange and pulmonary mechanics |
|-----------|------------------|----|-------------------|--------------------------------------|
| Type-L    | ![Type-L Chest Radiograph](image1.png) | ![Type-L CT](image2.png) | ![Type-L Low Flow PV Curve](image3.png) | • PF ratio=11.8 kPa  
• Cstat=37.9 ml cm H$_2$O$^{-1}$  
• C20/Cstat=1.06  
• LIP=2 cm H$_2$O  
• R/I ratio=0.02 |
| Type-H    | ![Type-H Chest Radiograph](image4.png) | ![Type-H CT](image5.png) | ![Type-H Low Flow PV Curve](image6.png) | • PF ratio=8.6 kPa  
• Cstat=10.4 ml cm H$_2$O$^{-1}$  
• C20/Cstat=0.82  
• LIP=11 cm H$_2$O  
• R/I ratio=0.72 |

---

**Fig 2.** Comparison of two typical coronavirus disease 2019 (COVID-19) patients with the Type-L and Type-H phenotypes contrasting chest radiographs, CT, quasi-static pressure-volume loop, gas exchange, and pulmonary mechanics ($P_{a}O_2$/FiO$_2$, Cstat, static lung compliance; C20/Cstat, ratio of static compliance in the last 20% of inspiration to total compliance; LIP, lower inflection point; R/I ratio, recruitment-to-inflation ratio).
counteracts the renin-angiotensin-aldosterone system through conversion of angiotensin-I and -II to angiotensin-(1–9) and -(1–7), respectively, these then promote localised vasodilatation and attenuation of the immune response. The initial downregulation of ACE2 results in angiotensin-II accumulation with resulting chemotactic effects and accelerated lymphocyte recruitment. The resulting pulmonary vascular inflammation results in an ACE1 ‘shedding’ phenomenon where endothelial surface-bound ACE1 is released into the interstitium and ultimately results in sub-physiologic angiotensin-II concentrations. Low angiotensin-II concentrations in this phase lead to vasodilatation and worsened capillary leak.

- The high incidence of pulmonary microvascular and macrovascular thrombosis offers insight into the high compliance, increased dead space, D-dimer elevation, and right ventricular dysfunction frequently observed in COVID-19 and documented in post-mortem findings and histology.

- The neurotropic potential of SARS-CoV-2 with altered central control of breathing mediated by pontine pneumotaxic centre dysfunction which results in increased tidal volumes relative to ventilatory frequency. Although low pulmonary elastance partially explains the deceptively effortless work of breathing, whilst surface-bound ACE1 is released into the interstitium, low angiotensin-II concentrations in this phase lead to vasodilatation and worsened capillary leak.

- Increased basal metabolic rate resulting in higher tissue oxygen extraction, lower mixed venous oxygen content, and increased venous admixture.

- Increased intrapulmonary shunt fraction with cardiac output impairment. Although high peripheral oxygen extraction partially explains the increased venous admixture observed in catabolic states, there may also be alterations in regional pulmonary blood flow distinct from this related to increased cardiac output. The contributions oxygen extraction and cardiac output play on arterial oxygen content can be seen when the Fick equation is rearranged: $\text{CaO}_2 = \text{CvO}_2 + \text{VO}_2/\text{CO}$. 

- Iatrogenic component through excess PEEP application to compliant non-atelectatic alveoli resulting in over-distention, increased dead space ventilation, and modification of shunt fraction because of redistribution of pulmonary perfusion.

Whilst many will recover from the type-L pattern with supportive measures, a proportion of patients will progress through to the type-H pattern. These two phenotypes do not represent discrete entities but a continuum, with a transition typically mediated by injurious organ support and hyper-inflammatory states. With the transition there are a number of associated changes in radiography and pulmonary mechanics outlined in Figure 2. The type-H phenotype more closely resembles ‘classical’ ARDS on CT with high EVLW, atelectasis, and increased non-aerated pulmonary units in the dependent areas, which results in significantly smaller normally aerated lung volume, high elastance, and higher potential for lung recruitment. This late phase three deterioration in pulmonary mechanics and oxygenation often coincides with referral for ECMO in our experience, typically 4–8 days after initiation of invasive ventilation. The early identification of other distinct CT patterns, such as acute interstitial pneumonia or cryptogenic organising pneumonias, is important for detecting any associated interstitial lung disease component and accelerated fibrosis that may benefit from a tailored immunomodulation strategy (Fig. 3).

With the heterogenous disease behaviour observed, it follows that the intensive care support and therapies should be tailored accordingly (Fig. 4). If significant hypoxaemia or work of breathing persists despite conventional oxygen therapy and a time-limited trial of awake prone position, the authors believe that intubation should not be delayed. A peripheral oxygen saturation (SpO₂) less than 92% on a non-re-breather mask (FiO₂ approximately 0.8) already represents a shunt fraction greater than 30%. In addition, the typical response to
Fig 4. Guy’s and St. Thomas’ NHS Foundation Trust suggested management of respiratory failure in coronavirus disease 2019 (COVID-19). CRT, critical care response team; ECMO, extracorporeal membrane oxygenation; ED, emergency department; HCID, high consequence infectious disease; HDU, high dependency unit; MERIT, mobile emergency response intubation team; MV, minute ventilation; NRBM, non-re-breather mask; PBW, predicted body weight; RM, recruitment manoeuvre; RR, respiratory rate; Vt, tidal volume; VV-ECMO, venovenous extracorporeal membrane oxygenation.
hypoxaemia when combined with high compliance is to generate excessively high intrapleural pressures which result in substantial pulmonary strain.30 If these large transpulmonary pressures are left unchecked, they can result in significant patient self-inflicted lung injury.20,39,40 Injurious spontaneous breathing has been shown to be associated with a deterioration in radiological appearances and diffuse alveolar damage at post-mortem.21,40 Timely intubation and institution of LPV can overcome many of these problems.

The high shunt fraction with limited atelectasis and recruitability, combined with a protracted disease course and high transpulmonary pressures in spontaneous respiration, would question the role of prolonged noninvasive ventilation (NIV) or CPAP in early disease. The use of NIV in moderate-severe de novo hypoxaemic respiratory failure has also been consistently associated with high failure rates and increased mortality, particularly when associated with tidal volumes greater than 9 ml kg\(^{-1}\) if there is no reduction in the amplitude of the oesophageal pressure swings.30,41 In the Intensive Care National Audit and Research Centre (ICNARC) report of 10 624 COVID-19 patients admitted to critical care in the UK, 84.7% of patients presented with moderate-severe hypoxaemic respiratory failure with a \(P_{a,\text{FIO}_2}\) ratio less than 26.7 kPa.1 In addition, any strategy involving wide-scale use of NIV should give consideration to the increased risk of aerosol generation and SARS-CoV-2 transmission,42 and the potential impact on institutional oxygen supplies.

After intubation, early LPV must be meticulously adhered to, given the propensity for beta-coronavirus infections to behave like an inflammatory lung disease,43 which makes them extremely susceptible to ventilator-induced lung injury and biotrauma. Initially deep sedation and liberal use of neuromuscular block should be used to facilitate LPV, and to avoid dys-synchrony and dramatic swings in transpulmonary pressures. In the event of progressive hypoxaemia, the use of strategies involving prone position, inhaled pulmonary vasodilators, higher mean airway pressures, and ECMO should be tailored to disease behaviour (Fig. 4). The authors adapt ventilation strategies based on an assessment of radiology and bedside pulmonary mechanics, including interrogation of quasi-static pressure–volume curves and recruitment-to-inflation ratios.44 In the Type-L phenotype with low elastance and recruitment-to-inflation ratio less than 0.5, strategies involving high PEEP typically result in limited alveolar recruitment with over-distention, increased dead space ventilation, and worsening venous admixture. To limit this unnecessary mechanical power application, the authors generally utilise a lower PEEP (5–10 cm H\(_2\)O), inhaled pulmonary vasodilators, and early prone position combined with standard tidal volume targets (6–8 ml kg\(^{-1}\)). Type-H phenotypes with high elastance and recruitment-to-inflation ratio greater than 0.5, are more receptive to typical ARDS ventilation strategies including higher PEEP (10–15 cm H\(_2\)O) and prone position while maintaining a plateau pressure less than 30 cm H\(_2\)O and tidal volume of 6 ml kg\(^{-1}\). When severe hypoxaemia is associated with persistent hyperthermia, a hypermetabolic state, and hyperdynamic cardiac output, the authors use surface or endovascular cooling devices to limit oxygen consumption, improve mixed venous oxygenation, and improve venous admixture.34 In SRF refractory to these conventional strategies, the authors have initiated mobile ECMO in 58 COVID-19 patients to date. Survival to critical care discharge was achieved in 42 of the 57 (73.7%) patients; with one patient still currently being supported on ECMO.

Given the unusual pulmonary mechanics and propensity for exaggerated inflammatory response, the timing of spontaneous breathing and extubation can be challenging in COVID-19. The initial improvements often observed with invasive ventilation can be falsely reassuring, resulting in premature deleterious spontaneous breathing and extubation attempts.45 The authors believe that overreliance on pulmonary mechanics and oxygenation indices for assessing weaning readiness in isolation is flawed, and that other surrogates for disease resolution are needed. The authors regard an improving trajectory in radiological appearances and ‘inflammatory panel’ (temperature, C-reactive protein [CRP], ferritin, triglycerides, and lactate dehydrogenase) as vital preconditions that should be assessed before undertaking any weaning attempts. Once spontaneous breathing is deemed appropriate, the use of \(P_{\text{musc}}\) Index and PO.1 can be particularly helpful to limit injurious breathing patterns and ensure ongoing LPV.46 With preconditions met and spontaneous breathing successfully initiated, a clear sensorium combined with an improved shunt fraction and tolerance of lower PEEP are particularly pertinent to extubation decisions. In patients with more extensive ICU-acquired weakness (ICU-AW) and greater risk of extubation failure, other traditional parameters for extubation readiness may also be helpful.47 Prophylactic dexamethasone administration should be considered peri-extubation given the increased incidence of glottic oedema associated with prolonged periods of intubation and prone positioning.48

### Cardiovascular system

The cardiovascular manifestations of SARS-CoV-2 are less frequent than that of the respiratory system, with an increased troponin occurring in 27.3% of hospitalised patients.48 These patients have an increased in-hospital mortality compared with those with normal troponins (59.6% and 8.9%, \(P<0.001\)).48 Although direct cardiovascular complications can be conveniently divided into categories (i.e. myopericarditis, ischaemic, and arrhythmias49), there is likely to be significant overlap between these groups.

There are no publications describing myocardial interstitial mononuclear inflammatory cell infiltrates and viral inclusions in COVID-19.50,51 Some of these changes are similar to those observed in classic viral myocarditis presenting with ECG alterations, depressed systolic function, biomarker leak, and cardiogenic shock.52 The proportion of myocardial necrosis related to direct viral cytopathy vs later molecular mimicry and dysregulated immune response varies amongst viruses.52 Whilst there have been a few reported cases of fulminant myocarditis presenting with low cardiac output states, dramatic elevations of troponin and N-terminal pro-brain natriuretic peptide (NT-proBNP),51,53,54 the vast majority of patients admitted with cardiac injuries present with only a mild biomarker leak, absent ECG changes, and preserved systolic function.52 In addition, the authors have observed four COVID-19 myopericarditis cases with precipitous cardiovascular collapse and pericardial tamponade necessitating emergent pericardiocentesis.

The ischaemic cardiac injury observed in COVID-19 likely represents a range of disease pathogenesis including inflammatory myocarditis. Myocardial infarctions mediated by atherosclerotic plaque rupture and coronary thrombus or type II pattern related to flow-demand imbalance, are often observed in acute respiratory illnesses.55 The linear correlation between troponin and CRP does, however, pose the
interesting question whether the majority of cardiac injuries are merely the consequence of an exaggerated immune response, and surrogate of disease severity and organ dysfunction, rather than a distinct entity. The culmination of these mechanisms contributes to the 17.3% of patients with elevated troponin experiencing ventricular fibrillation or ventricular tachycardia during hospitalisation. In 136 COVID-19 patients with witnessed in-hospital cardiac arrests, the initial rhythm was shockable, asystole, and pulseless electrical activity in 5.9%, 89.7%, and 4.4%, respectively. Accounting for the higher proportion of primary respiratory events, there was still a disproportionate rate of asystole compared with non-COVID-19 in-hospital cardiac arrest data. The authors have witnessed a number of sudden non-shockable cardiac arrests in previously fit and well young COVID-19 patients without preceding respiratory embarrassment, significant echocardiographic or ECG findings, and only mild troponin release. Published cardiovascular pathogenesis in COVID-19 cannot fully explain such unpredictable disease behaviours. A number of these patients have presented with symptoms compatible with meningoencephalitis, a recognised complication of COVID-19, and the authors hypothesise such precipitous cardiovascular collapse could be partly mediated by neurocardiac axis dysfunction as a result of vasomotor centre injury in the rostral ventrolateral medulla, as seen in other viral-induced rhombencephalitis.

The influence of cardiopulmonary interactions observed in critical illness must also be considered in COVID-19. Clinicians should remain vigilant for the development of acute cor pulmonale given the high incidence of thrombotic pulmonary complications combined with frequent hypoxaemia, hypercarbia, and elevated intrapulmonary pressures. Early therapies to optimise pulmonary vascular resistance and right ventricular function are key to avoiding ventricular uncoupling and worsening multiorgan dysfunction syndrome. Early bedside echocardiographic assessment in patients with high acute cor pulmonale scores or escalating vasoactive drug requirements is essential to facilitate timely resuscitation. Therapies for acute right ventricular dysfunction in the context of pulmonary hypertension should be multifaceted: 1. Treatment of specific aetiologies. 2. Optimise intravascular volume and venous capacitance. 3. Optimise inotropy with a preference for phosphodies- terase III inhibitors or levosimendan. 4. Minimise right ventricular afterload through ventilatory manipulation to optimise functional residual capacity, limit intrathoracic pressures, and achieve normocarbia/ normoxia. 5. Prone position to improve right ventricular pressure overload. 6. Reduction in pulmonary vascular resistance through inhaled or systemic pulmonary vasodilators, and a preference for vasopressin over catecholaminergic agents if a systemic vasopressor is required. 7. Temporary percutaneous and extracorporeal life support.

Given the overwhelming volume of admissions and low incidence of cardiovascular derangement observed in COVID-19, a standardised approach to general haemodynamic support is suitable for the majority of patients.

In the later phase of the COVID-19 pandemic, a number of patients (predominantly children and adolescents) have presented with a prior respiratory illness followed many weeks later by gastrointestinal symptoms, fever, and acute heart failure; this syndrome has been since been named paediatric multisystem inflammatory syndrome temporally associated with SARS-CoV-2. Ten young patients have been referred to our ECMO service with similar symptomatology, severe left ventricular systolic dysfunction, and a high CRP and ferritin. These patients have all responded to a combination of i.v. immunoglobulin, methylprednisolone, and inpressors. Depending on the mode and severity of the cardiovascular decline, a strategy including extracorporeal life support may also be appropriate. Although a proportion of these cases may represent a classical viral myocarditis, there is growing interest in the possibility of a distinct vasculitic process such as Kawasaki disease shock syndrome. If this presentation is combined with SARS-CoV-2 IgM, IgG positivity, or both, and any mucocutaneous features (strawberry tongue, conjunctivitis, and palmar or plantar erythema), consideration should also be given to high-dose aspirin and a follow-up CT coronary angiogram to exclude coronary aneurysms.

**Neurological system**

Neurological symptoms occur in up to 36.4% of patients presenting with COVID-19, and these are more prevalent in those with severe disease. These complications appear to be mediated by either an anoxic injury or SARS-CoV-2 neurotropism through haematogenous and retrograde neuronal infiltration. The pathogenesis of the anoxic injury could be global oxygen delivery issues or more territorial related to cardioembolic disease and primary in situ thrombosis. The neurological consequences of these can include meningoencephalitis, HLH, and cerebrovascular infarcts and bleeds. The authors have sadly seen three catastrophic multi-territory strokes in patients with severe COVID-19; all patients were under the age of 35, with no cardiovascular risk factors or echocardiogram abnormalities detected.

For the majority of neurological emergencies in COVID-19 the treatment will be supportive. Maintaining homeostasis with a particular focus on gas exchange and blood pressure optimisation is essential to limiting secondary brain injury. In patients presenting with strokes, the complex decision-making around the timing of anticoagulation, and the role of mechanical thrombectomy and surgery are best addressed in high volume centres.

COVID-19 can present significant sedation challenges given the need for deep planes of anaesthesia in hypermetabolic patients. Despite the use of propofol 2% and a strict upper dose limit of 5 mg kg⁻¹ h⁻¹, the authors have observed high rates of hypertriglyceridaemia. This elevation likely reflects exaggerated macrophage activation rather than evolving propofol-related infusion syndrome. However, given the high prevalence of risk factors for propofol-related infusion syndrome in COVID-19, it would seem prudent to utilise adjunctive sedatives such as alpha-2 agonists, benzodiazepines, or ketamine early to limit the lipid load when hypertriglyceridaemia develops. Reducing lipid intake and modulating the underlying disease process are the primary therapeutic strategies for hypertriglyceridaemia in critical illness. In patients requiring ECMO support with hypertriglyceridaemia, the authors initiate fenofibrate given the increased risk of mechanical failure of extracorporeal circuits and potential novel protective effect in acute lung
injury through restoration of free fatty acid oxidation.\textsuperscript{77} Vol-
atile anaesthesia use in intensive care has a growing evidence base,\textsuperscript{78} and where the depth of sedation is difficult to attain
without significant side-effects in COVID-19, they have been
delivered locally with the AnaConDa\textsuperscript{®} (Sedana Medical, Ven-
devägen 87, SE-182 32 Danderyd, Sweden) system to good
effect.

Renal system

Acute kidney injury (AKI) has emerged as a serious complication
in critically ill patients with COVID-19. The prevalence is variable
with an incidence of less than 5\% in some initial reports from
China, to greater than 20\% in more contemporary UK data-
sets.\textsuperscript{5,11} This variation may be explained by differences in clinical
practice, but there also appear to be socioeconomic and genetic
components. ACE2 receptor expression in renal podocytes and
proximal tubule cells is more pronounced in Occidental subjects
than in Asians, suggesting that the risk of COVID-19-associated
AKI may differ between different ethnic groups.\textsuperscript{79}

The aetiology of COVID-19-related AKI is multifactorial and
includes haemodynamic disturbance, inflammation, cytokine
release, endothelial dysfunction, alteration of the microcir-
nulation, nephrotoxic exposure, and the impact of invasive
mechanical ventilation.\textsuperscript{80–82} Although these factors are
similar to AKI in non-COVID-19 settings, it appears there are
additional factors specific to SARS-CoV-2:

\begin{itemize}
  \item The SARS-CoV-2 virus uses ACE2 as a cell entry receptor. After entry into the tubular epithelium and podocytes, the virus may exert direct cytopathic effects in the kid-
ney.\textsuperscript{83} The deposition of immune complexes of viral anti-
gen or virus-induced specific immunological effector
mechanisms (specific T-lymphocytes, complement C5b-
9, or antibodies) may cause additional damage.\textsuperscript{83,84}
  \item ACE2 is pivotal in the conversion of angiotensin-II to the
vasodilatory and anti-inflammatory peptide angiotensin-
(1–7). With ACE2 downregulation there is an initial in-
crease in local angiotensin-II concentration associated
with vasoconstriction, endothelial activation, and cyto-
kinemia.\textsuperscript{85} With evolving pulmonary vascular inflam-
ination and ACE-1 ‘shedding’ there is an eventual decrease in angiotensin-II concentration to sub-
physiologic concentrations.\textsuperscript{86} This results in vasodila-
ition, worsened capillary leak, alteration of glomerular
autoregulation, and reduction of glomerular filtration.
  \item Renovascular microthrombi. Post-mortem studies have
shown segmental fibrin thrombi and erythrocyte aggre-
gates obstructing peritubular capillaries and impacting
intrarenal microcirculation.\textsuperscript{83}
  \item Rhabdomyolysis. Some reports of renal histology
demonstrated pigmented tubular casts containing high
concentrations of creatine phosphokinase.\textsuperscript{85}
  \item Collapsing glomerulopathy, an aggressive variant of focal
segmental glomerulosclerosis with high rates of podo-
cyte injury and depletion, has also been reported in renal
biopsies.\textsuperscript{87}
\end{itemize}

Presently, there is no specific treatment for COVID-19
associated with AKI, although several potential therapies tar-
geting different aspects of the pathophysiology are being
explored.\textsuperscript{88–90} Intravascular volume, microvascular flow, and
perfusion pressure should be optimised and if renal replace-
ment therapy (RRT) is required, there is no evidence that a
particular timing, mode, or dose is superior, but adjustments
may need to be made in case of reduced RRT capacity.\textsuperscript{91,92}
Given the frequent thrombotic loss of extracorporeal circuits
in COVID-19\textsuperscript{93} the authors have a low threshold for initiating
systemic anticoagulation alongside regional citrate if prob-
lems are encountered.

COVID-19-related AKI is associated with an increased risk of
mortality especially if RRT is required.\textsuperscript{93} The long-term impact
on kidney function, risk of chronic dialysis, cardiovascular
morbidity and mortality remain unknown at this stage.

Haematology

There is escalating concern over thrombotic complications in
COVID-19 related to the intricate interplay between cytopathic
ACE2-related endotheliopathy, hypoxic pulmonary vasocon-
striction, and the inflammatory response with procoagulant–anticoagulant disequilibrium. Initially, it was
reported that 71.4\% of COVID-19 deaths fulfilled the Interna-
tional Society on Thrombosis and Haemostasis criteria
for disseminated intravascular coagulation.\textsuperscript{94} However, a French
case series of 150 patients has since revealed no cases of
disseminated intravascular coagulation as defined by the
same score,\textsuperscript{95} and there have been no reported cases of the
classical hyperfibrinolytic consumptive process with bleeding
propensity.\textsuperscript{95} There has been renewed interest in D-dimer
concentrations given the significant elevation noted in pa-
tients admitted to intensive care and non-survivors.\textsuperscript{14,96} It re-
mains unclear what proportion of these D-dimer elevations
are related to thrombosis formation and fibrin turnover or
merely intense pulmonary inflammation. A number of pro-
coagulants have also been reported to be increased in COVID-
19 including fibrinogen, factor VIII, von Willebrand factor ac-
tivity and antigen, and interestingly, lupus anticoagulant and
anticardiolipin antibodies.\textsuperscript{93,97} Although the incidence of pro-
longed direct Russell viper venom time does seem particularly
high, caution must be exercised when interpreting a single set
of tests in the context of critical illness with acute viral in-
fecions, particularly given the lack of reporting of anti-\textbeta
-glycoprotein-1 titres. Furthermore, during significant inflam-
mation there is frequent impairment of endogenous antico-
agulant pathways such as activated protein C, antithrombin
III, and tissue factor pathway inhibitor.\textsuperscript{98}

There is a growing body of evidence suggesting a significant
microvascular and macrovascular thrombus burden in
COVID-19.\textsuperscript{21,23,27–29,93,99,100} and this incidence exceeds those
observed in matched non-COVID-19 severe ARDS patients.\textsuperscript{21,93}
In addition to standard cross-sectional imaging, the authors
feel there is an emerging role for dual energy CT to better
delineate the presence of subtle perfusion defects and micro-
vascular thrombosis.\textsuperscript{101} The underlying mechanism as alluded
to is not fully understood but appears primarily immuno-
thrombotic in nature, culminating in high fibrinogen concen-
trations with hypercoagulability, endothelial injury, and
hypoxic pulmonary vasoconstriction with stasis. Tang and
colleagues\textsuperscript{102} suggested anticoagulation treatment may
reduce mortality in COVID-19 patients with ‘sepsis-induced
cogulopathy’ or elevated D-dimers but the dose of anti-
coagulation utilised constituted venous thromboprophylaxis.
Enhanced thromboprophylaxis may reduce fibrinogen and D-
dimer concentrations along with improving hypercoagulable
viscoelastic parameters,\textsuperscript{103} however, given the small sample
size and retrospective nature of this work, it remains unclear
whether this was causation or association. Upstream immu-
notherapy, particularly interleukin-6 (IL-6) modulation given
Fig 5. Anticoagulation strategy in coronavirus disease 2019 (COVID-19). CTPA, CT pulmonary angiogram; DECT, dual energy CT; eGFR, estimated glomerular filtration rate; LMWH, low molecular weight heparin; NTproBNP, N-terminal pro-brain natriuretic peptide; UFH, unfractionated heparin; VTE, venous thromboembolism.

Immunology

There is an increasing appreciation of the critical impact the host immune response has on illness severity and outcomes in COVID-19. Initial rapid SARS-CoV-2 replication results in activation of lymphocytes (natural killer, T-helper, and T-cytotoxic cells), release of a range of cytokines and chemokines, and in severe cases, lymphocyte exhaustion and peripheral lymphopaenia. In COVID-19, IL-1α/1ra/2/7/10/17, interferon-γ, inducible interferon protein-10, granulocyte colony-stimulating-factor, and monococyte chemoattractant peptide-3 concentrations are strongly associated with viral load and lung injury scores. Synergistic innate and adaptive immunity is an essential host response to ensure viral clearance. In a small proportion of patients this host response is either protracted or disproportionate with exaggerated monocyte activation and IL-6 production. Maladaptive macrophage activation can result in hyperinflammatory syndromes such as sHLH characterised by a persistent pyrexia, hyperferritinaemia, similar cytokine profiles, and organ dysfunction. The authors routinely screen all COVID-19 patients admitted to critical care for sHLH utilising the H-score, but in our experience only a small proportion of patients have scores greater than 169. High concentrations of IL-6 associated with decreased lymphocyte subsets, pyrexia, and organ dysfunction are critical components of CRS. While there has been much interest in COVID-19-related CRS and ‘cytokine storms’, the IL-6 concentrations and inopressor requirements in the majority of patients rarely approach those previously outlined in the CRS literature and are probably overstated. The authors feel while a generalised hyperinflammatory state in the context of persistent organ dysfunction associated with ongoing pyrexia and inflammation (raised CRP, hyperferritinaemia, and hypertriglyceridaemia) in the absence of demonstrable infection. The role of immunomodulation in maladaptive immune responses in COVID-19 remains controversial with a paucity of high-quality evidence. The WHO recommended against the use of corticosteroids, but this was largely based on concerns over increased viral shedding...
observed in Middle Eastern Respiratory Syndrome and an inconclusive systematic review in SARS-CoV-1. One of the largest studies of corticosteroids in SARS-CoV-1 has since been published demonstrating both safety and a decreased risk of death in severe disease (hazard ratio 0.53; 95% confidence interval 0.35–0.82). Prolonged use of corticosteroids in ARDS has also been previously associated with decreased mortality and healthcare utilisation. The authors believe this data, combined with the high incidence of acute fibrinous and organising pneumonia and preliminary evidence of improved outcomes in COVID-19, the judicious use of corticosteroids in patients with hyperinflammatory disease behaviour. The dose of methylprednisolone utilised locally is 1 mg kg⁻¹ day⁻¹ in early disease or 2 mg kg⁻¹ day⁻¹ if initiated late in patients with persistent SRF. After 5 days at this dose, the methylprednisolone is then weaned over 3 weeks. Reassuringly, this approach is supported by recent initial reports from the ‘randomised evaluation of COVID-19 therapy’ (RECOVERY) trial which suggested early, low-dose dexamethasone can improve survival in COVID-19 patients, with a number needed to treat of 8.5 in those requiring invasive mechanical ventilation. When deciding on the timing of immunomodulation, integration of proactive surveillance for intercurrent infections with procalcitonin, microbiological cultures, cytomegalovirus viral load, and fungal serology is essential. The use of high-dose corticosteroids, i.v. immunoglobulin, anakinra (IL-1 receptor antagonist), or tocilizumab (IL-6 receptor antagonist) is reserved locally for patients with more overt features of sHLH or CRS.

The use of vitamin C in severe ARDS may attenuate cytokine surges, and limit activated neutrophil accumulation and extracellular trap formation. These mechanisms may improve alveolar fluid clearance and limit endothelial injury. In the CITRIS-ALI trial, although the use of vitamin C in ARDS was not associated with an improvement in any of the primary outcomes, there was a significant reduction in 28-day mortality. Given the perceived benefits and favourable safety profile, we tend to administer Pabrinex® to COVID-19 patients with organ dysfunction, particularly in the context of increased thiamine losses with diuresis or RRT.

Whilst the use of antivirals to limit replication, cytopathic injury, and immune response would seem intuitive, initial RCTs of remdesivir and Kaletra proved disappointing. However, the recent ‘adaptive COVID-19 treatment trial’ showed that remdesivir was associated with a reduced time to recovery and non-significant reduction in mortality. The median in recovery time from 15 to 11 days is a particularly meaningful endpoint in the resource limited backdrop of a pandemic. The impact on outcome was greatest in patients in the initial phases of illness on oxygen therapy alone rather than those requiring ventilation or ECMO.

The ongoing and wider use of other novel therapies such as macrolides, hydroxychloroquine, interferon-β-1a, anakinra, tocilizumab, sarilumab, or convalescent plasma should be limited to prospective clinical trials such as the ‘randomised, embedded, multifactorial, adaptive platform trial for community acquired pneumonia’ (REMAP-CAP).

**Conclusion**

COVID-19 is a complex multisystem inflammatory and microvascular disease conferring a significant mortality. A greater understanding of pathogenesis, combined with evidence-based organ support and tailored therapies where appropriate, will optimise outcomes in the later stages of the pandemic.

**Authors’ contributions**

Conceived the idea for the manuscript: PBS

Involved in the literature review and drafting of the manuscript: all authors

Reviewed and approved the final manuscript for publication: all authors

**Declarations of interest**

The authors declare that they have no conflicts of interest. The views expressed in the submitted article are his or her own and not an official position of the institution or funder. Ethical approval was not required given nature of the manuscript.

**Funding**

The authors received no grants, equipment, drugs and/or other support that facilitated conduct of the work described in the article or the writing of the article itself.
