\[ \text{ABSTRACT} \]

The chemical properties of high-\( z \) galaxies provide important information for constraining galaxy evolutionary scenarios. However, widely used metallicity diagnostics based on rest-frame optical emission lines are unusable for heavily dust-shrouded galaxies (such as submillimeter galaxies; SMGs), especially at \( z > 3 \). Here we focus on the flux ratio of the far-infrared fine-structure emission lines \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) and \([\text{C}\,\text{ii}]\,158\,\mu\text{m}\) to assess the metallicity of high-\( z \) SMGs. Through ALMA cycle 0 observations, we have detected the \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) emission in a strongly \([\text{C}\,\text{ii}]\)-emitting SMG, LESS J033229.4–275619 at \( z = 4.76 \). The velocity-integrated \([\text{N}\,\text{ii}]/[\text{C}\,\text{ii}]\) flux ratio is 0.043 \( \pm \) 0.008. This is the first measurement of the \([\text{N}\,\text{ii}]/[\text{C}\,\text{ii}]\) flux ratio in high-\( z \) galaxies, and the inferred flux ratio is similar to the ratio observed in the nearby universe (\( \sim 0.02–0.07 \)). The velocity-integrated flux ratio and photoionization models suggest that the metallicity in this SMG is consistent with solar, implying that the chemical evolution has progressed very rapidly in this system at \( z = 4.76 \). We also obtain a tight upper limit on the \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) emission by the radiation field emitted by the AGN in this system.

\[ \text{Key words. galaxies: high-redshift – galaxies: individual: LESS J033229.4–275619 – submillimeter: galaxies – submillimeter: ISM} \]

1. Introduction

Investigating the metal content in galaxies is a powerful diagnostic for testing galaxy evolutionary models, because the metallicity is determined by the past star-formation history, gas inflow, and outflow phenomena. The gas metallicity in galaxies has been investigated in galaxies up to \( z \sim 3 \) (Maiolino et al. 2008; Mannucci et al. 2010). However, rest-frame optical metallicity diagnostics (e.g., Nagao et al. 2006a) are not applicable for galaxies at \( z > 4 \), where the optical emission lines required to measure the metallicity are redshifted out of the near-infrared atmospheric window (see Maiolino et al. 2008). Moreover, high-\( z \) young galaxies with vigorous star formation are often obscured by dust and recognized as, e.g., ultraluminous infrared galaxies (ULIRGs) and submillimeter galaxies (SMGs). In these galaxies, the rest-frame optical lines are significantly affected by the dust extinction and accordingly the optical metallicity diagnostics may lead to large systematic errors. For instance, it has been claimed that ULIRGs show systematically lower metallicities than expected from the mass-metallicity relation (Rupke et al. 2008; Caputi et al. 2008); but this may simply be a consequence of the fact that in these heavily obscured systems the optical metallicity tracers only probe the outer, less enriched regions. Santini et al. (2010) reported that the high dust mass measured in these galaxies disagrees with the metallicity inferred from the optical metallicity diagnostics, suggesting that the optical spectral indices are likely unreliable in these dusty systems.

Metallicity diagnostics exploiting far-infrared fine-structure emission lines are powerful alternatives (Nagao et al. 2011). Here we focus on the two strongest fine-structure lines at \( \lambda_{\text{rest}} > 150\,\mu\text{m} \), i.e., \([\text{C}\,\text{ii}]\,158\,\mu\text{m}\) and \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\). The \([\text{C}\,\text{ii}]\,158\,\mu\text{m}\) emission (\( \lambda_{\text{rest}} = 1900.539 \,\text{GHz} \)) is one of the strongest lines among the whole electromagnetic spectrum and is consequently observed for some high-\( z \) objects even up to \( z \sim 6–7 \) (Maiolino et al. 2005; Walter et al. 2009a; Venemans et al. 2012). This emission arises mainly in H\,\text{n} regions and photodissociation regions (PDRs), and the relative contribution from these two regions depends on the physical conditions of gas clouds (e.g., Abel et al. 2005). The \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) emission (\( \lambda_{\text{rest}} = 1461.132 \,\text{GHz} \); Brown et al. 1994) arises in H\,\text{n} regions (see Nagao et al. 2011). In H\,\text{n} regions, the \([\text{N}\,\text{ii}]/[\text{C}\,\text{ii}]\) flux ratio depends mostly on the N/C elemental abundance ratio, while it is relatively insensitive to other gas physical conditions such as the gas density, since their critical densities are similar (\( n_{\text{cr}} = 44 \,\text{cm}^{-3} \) and 46 \,\text{cm}^{-3} \) for \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) and \([\text{C}\,\text{ii}]\,158\,\mu\text{m} \)); at 8000 K, respectively). Note that the N/C ratio is proportional to \( Z_{\text{gas}} \) at least for \( \log Z_{\text{gas}}/Z_{\odot} > -0.5 \) as observed in Galactic H\,\text{n} regions (e.g., van Zee et al. 1998) because nitrogen is a secondary element (see also Hamann & Ferland 1999). Since the volume ratio of H\,\text{n} regions and PDRs also depends on cloud properties such as the gas density and ionization structure (hence the ionization parameter), the observed \([\text{N}\,\text{ii}]/[\text{C}\,\text{ii}]\) flux ratio accordingly depends on those parameters. Recently, \([\text{N}\,\text{ii}]\,205\,\mu\text{m}\) detections have been obtained for three strongly lensed galaxies at \( z \sim 4–5 \) (Decarli et al. 2012; Combes et al. 2012); however a \([\text{C}\,\text{ii}]\,158\,\mu\text{m}\) detection has not been reported in any of these galaxies.

Here we show that the \([\text{N}\,\text{ii}]/[\text{C}\,\text{ii}]\) flux ratio is a good metallicity indicator based on photoionization models, and apply this new method to a high-\( z \) luminous SMG.
LESS J03329.4–275619 (hereafter LESS J0332). We selected this SMG because this object is starburst-dominated and shows intense [C\textsc{ii}] 158 \mu m emission (De Breuck et al. 2011), making this SMG a good target for the [N\textsc{ii}] 205 \mu m observation. In this Letter we report a clear [N\textsc{ii}] 205 \mu m detection based on our ALMA cycle 0 observation, and discuss the chemical property of a high-z SMG. Throughout this Letter, we adopt a cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, and $\Omega_k = 0.73$.

2. Observations and results

We observed LESS J0332 at $z = 4.76$, with the band 6 receiver on the Atacama Large Millimeter/submillimeter Array (ALMA) in the dual-polarization setup, as a cycle 0 program. The observation was carried out in three separated runs; on 2011 October 1, 2012 January 12, and 2012 January 13. Each observing run consisted of 1.2 h and the total observing time is 3.6 h, including overheads. The receiver was tuned to 253.96001 GHz to cover the redshifted [N\textsc{ii}] 205 \mu m emission with the upper sideband, whose redshift is based on our previous [C\textsc{ii}] 158 \mu m detection (De Breuck et al. 2011). The lower sideband was used to cover the redshifted CO(12–11) emission ($\nu_{\text{rest}} = 1381.995$ GHz). The correlator was used in the frequency domain mode with a bandwidth of 1875 MHz (488.28 kHz $\times$ 3840 channels). The observation was performed with 18 antennas in the compact configuration, but the data obtained with one antenna was flagged out in the last run due to its high system temperature. Callisto was also observed as a flux calibrator. The bandpass and phase were calibrated with J0522–364 and J0403–360, respectively. The atmospheric condition was PWV = 3.0–5.0 mm in the first run and PWV = 1.0–2.0 mm for the last two runs.

The data were processed with Common Astronomy Software Applications (CASA; McMullin et al. 2007; Petry & the CASA Development Team 2012) in a standard manner. A 70-channel (or equivalently, 40.54 km s$^{-1}$) binning was applied to the data cube, and then the clean process was applied with the natural weighting, which gives a final synthesized beam size of $1.67'' \times 1.48''$ (position angle = 26.8 degree). The [N\textsc{ii}] 205 \mu m emission of LESS J0332 is clearly detected in the continuum-subtracted binned channel map, as shown in Fig. 1.

Figure 2 shows the [N\textsc{ii}] 205 \mu m spectrum of LESS J0332 adopting an aperture size of 4.8 arcsec$^2$, with the previously reported spectra of CO(2–1) (Coppin et al. 2010) and [C\textsc{ii}] 158 \mu m (De Breuck et al. 2011). The [N\textsc{ii}] 205 \mu m detection significance is $\sim 8\sigma$. The emission line is fitted with a single Gaussian profile. The best-fit result is parameterized by the peak frequency of 253.868 $\pm$ 0.007 GHz, peak intensity of 2.58 $\pm$ 0.21 mJy, FWHM of 230 $\pm$ 22 km s$^{-1}$, and the velocity-integrated flux of 630 $\pm$ 78 mJy km s$^{-1}$. The redshift inferred from the observed [N\textsc{ii}] 205 \mu m frequency is $z_{\text{[NII]}} = 4.7555 \pm 0.0002$, which is significantly blueshifted from the Ly$\alpha$ redshift. This blueshift is probably caused by the Ly$\alpha$ absorption by the intergalactic neutral hydrogen. The redshift is consistent with the CO(2–1) redshift, though there is a velocity offset, significant at $\sim 2\sigma$, between the [N\textsc{ii}] 205 \mu m and [C\textsc{ii}] 158 \mu m lines. This velocity offset may be a consequence of the modest signal-to-noise ratio in the two spectra, especially in the [C\textsc{ii}] spectrum. Forthcoming [C\textsc{ii}] ALMA observations of the same objects will either confirm or reconcile the velocity discrepancy. However, if this velocity offset is confirmed, this results in different [N\textsc{ii}]/[C\textsc{ii}] flux ratios in the blue and red components (see Sect. 3.2).

The redshifted CO(12–11) emission is not detected in our ALMA data. The inferred $3\sigma$ upper limit on the velocity-integrated flux is 344 mJy km s$^{-1}$ (adopting the same aperture size as adopted for the [N\textsc{ii}] 205 \mu m line and assuming the same velocity profile).

The continuum emission at $\lambda_{\text{obs}} \sim 1.2$ mm (i.e., $\lambda_{\text{rest}} \sim 210 \mu$m) is clearly detected with high accuracy. Its flux is 3.5 $\pm$ 0.1 mJy with the same aperture as adopted for the [N\textsc{ii}] 205 \mu m measurement. These measurements were made by combining the upper and lower sideband data and excluding the channels affected by the [N\textsc{ii}] 205 \mu m emission and by a relatively high noise level at the edges of the sidebands.

Both the [N\textsc{ii}] 205 \mu m emission and the continuum emission are unresolved at our angular resolution. The two-dimensional Gaussian fit on the velocity-integrated images results in the major and minor axis FWHMs of 1.86 $\pm$ 0.44 arcsec and 1.31 $\pm$ 0.47 arcsec for the [N\textsc{ii}] 205 \mu m emission, and 1.72 $\pm$ 0.19 arcsec and 1.55 $\pm$ 0.21 arcsec for the continuum
emission. Both results are consistent with the synthesized-beam image shape.

3. Discussion

3.1. Possible AGN contribution

Gilli et al. (2011) reported the presence of a Compton-thick active galactic nucleus (AGN) in LESS J0332. If the AGN contributes significantly to the observed far-IR emission lines, its interpretation would become accordingly more complex. Within this context the CO spectral line energy distribution can help, since it is sensitive to the heating energy source. CO lines at high excitation levels are significantly stronger when the molecular gas clouds are affected by the X-ray emission from AGNs than in cases without AGNs (see, e.g., Spaans & Meijerink 2008). The nearby ULIRG-Quasar Mrk 231 shows strong high-J CO lines up to $J=13-12$, which are properly accounted for by introducing X-ray dominated regions (XDRs) into models (van der Werf et al. 2010). At high-$z$ the gravitationally magnified quasar at $z=3.91$, APM 08279+5255 also shows strong high-J CO lines (Weiß et al. 2007; Bradford et al. 2011), which are also well described by XDR models. The CO spectral line energy distribution of other star-formation-dominated high-$z$ galaxies, such as SMM J1635+6612 at $z=2.5$ (Weiß et al. 2005) and IRAS F1021+4724 at $z=2.3$ (Ao et al. 2008), is completely different from that of APM 08279+5255, showing weaker high-J CO lines (see, e.g., Fig. 14 in Weiß et al. 2007).

By combining our upper limit on the CO(12−11) flux and the previous measurement of the CO(2−1) flux (Coppin et al. 2010), we obtain a $3\sigma$ upper limit on the flux ratio of CO(12−11)/CO(2−1) of 3.8. This upper limit is inconsistent with the CO spectral line energy distribution of the quasar APM 08279+5255, but is fully consistent with other star-formation-dominated high-$z$ objects (see Fig. 14 in Weiß et al. 2007). This suggests that the molecular clouds in LESS J0332 are not described by XDR models, i.e., the AGN contribution to the heating and excitation of the ISM in LESS J0332 is not significant. This is consistent with our earlier study on LESS J0332 (De Breuck et al. 2011), where we estimated that the XDR contribution to the [C II] 5142 + 23 at $z=3.91$, and MM 18423+5938 at $z=3.93$ (Decarli et al. 2012). However, their [C II] 158 $\mu$m line has not been observed and consequently their [N II]/[C II] ratio is unknown (see Walter et al. 2009b, and references therein). Therefore our [N II]/[C II] 205 $\mu$m detection allows us to infer the first measurement of the diagnostic [N II]/[C II] flux ratio at high-$z$. Note that there are many other AGNs in nearby galaxies (e.g., Graciá-Carpio et al. 2011) and also in a few high-$z$ galaxies (Ferkhioff et al. 2011). Although there are attempts to infer the [N II] 205 $\mu$m flux from the [N II] 122 $\mu$m emission (e.g., Decarli et al. 2012), this method may introduce a large systematic error because the flux ratio of [N II] 122 $\mu$m and [N II] 205 $\mu$m varies by a factor of ~10, i.e., it is strongly dependent on the gas density (see Oberst et al. 2006).

To explore the gas metallicity in LESS J0332 more quantitatively, we carried out model calculations using Cloudy (Ferland et al. 1998) version 08.00. Since the [C II] line arises in both H II regions and PDRs, a consistent treatment to connect those two regions is required to investigate the [N II]/[C II] flux ratio. We assumed a pressure-equilibrium gas cloud that is characterized by certain gas densities and ionization parameters at the illuminated face ($n_{\text{HII}}$ and $U_{\text{HII}}$) for each model run. Here we examine gas clouds with $\log n_{\text{HII}} = 1.5$ and 3.0, and $\log U_{\text{HII}} = -3.5$ and $-2.5$, for $Z_{\text{gas}}/Z_{\odot} = 0.05 - 3.0$. Note that the gas density in PDRs is higher than $n_{\text{HII}}$ under.

Table 1. Observed properties of LESS J0332.4–275619.

| Parameter     | Value       | Reference         |
|---------------|-------------|-------------------|
| $\Delta z_{\text{AGN}}$ | 4.76±0.002 | Coppin et al. (2009) |
| $\Delta (\text{CO}(2-1))$ | 4.755±0.001 | Coppin et al. (2010) |
| $\Delta \text{CII}$   | 4.7534±0.0009 | De Breuck et al. (2011) |
| $\Delta \text{NII}$    | 4.755±0.0002 | this work         |
| $L_{\text{CO}(2-1)}$   | 0.09±0.02 Jy km s$^{-1}$ | Coppin et al. (2010) |
| $L_{\text{CII}}$       | 14.7±2.2 Jy km s$^{-1}$ | De Breuck et al. (2011) |
| $L_{\text{NII}}$       | 0.630±0.078 Jy km s$^{-1}$ | this work         |
| $L_{\text{CO}(2-1)}$   | <0.344 Jy km s$^{-1}$ (3$\sigma$) | this paper         |
| $L_{\Delta \text{CO}(2-1)}$ | 160±65 km s$^{-1}$ | Coppin et al. (2010) |
| $L_{\Delta \text{CII}}$ | 161±45 km s$^{-1}$ | De Breuck et al. (2011) |
| $L_{\Delta \text{NII}}$ | 230±22 km s$^{-1}$ | this work         |

Fig. 3. Observed [N II]/[C II] flux ratios compared with model predictions. The green dashed line denotes the observed range for low-$z$ galaxies. The horizontal dashed line shows our ALMA result on LESS J0332, where the emission-line fluxes are measured by integrating the best-fit Gaussian function. Dotted magenta lines denote the flux ratio at the red part (from $-350$ km s$^{-1}$ to $-150$ km s$^{-1}$) and blue part (from $-550$ km s$^{-1}$ to $-350$ km s$^{-1}$) of the lines. The red and blue lines show Cloudy model results as a function of $Z_{\text{gas}}$ with $\log n_{\text{HII}} = 1.5$ and 3.0 respectively, while solid and dashed lines denote the models with $\log U_{\text{HII}} = -2.5$ and $-3.5$, respectively.

3.2. Gas metallicity

Based on our [N II] 205 $\mu$m detection and our previous [C II] 158 $\mu$m detection (De Breuck et al. 2011) in LESS J0332, the velocity-integrated flux ratio of [N II]/[C II] is inferred to be $0.043±0.008$. Unfortunately, there are only few previous measurements on the [N II] 205 $\mu$m line in galaxies (mostly because this line was not covered by the ISO/LWS wavelength range). In the nearby universe, the flux ratio of [N II]/[C II] is reported only for M 82 (~0.050; Petuchowski et al. 1994), Mrk 231 (~0.067; Fischer et al. 2010), NGC 1097 (~0.017; Beirão et al. 2010), and Arp 220 (~0.059; Rangwala et al. 2011). Therefore the [N II]/[C II] flux ratio of LESS J0332 is similar to the observed ratios reported for nearby galaxies, suggesting similar $Z_{\text{gas}}$.

At high-$z$ [N II] 205 $\mu$m has been detected in HLS J091828.6+514223 at $z=5.24$ (Combes et al. 2012), APM 08279+5255 at $z=3.91$, and MM 18423+5938 at $z=3.93$ (Decarli et al. 2012). However, their [C II] 158 $\mu$m line has not been observed and consequently their [N II]/[C II] ratio is unknown (see Walter et al. 2009b, and references therein). Therefore our [N II]/[C II] 205 $\mu$m detection allows us to infer the first measurement of the diagnostic [N II]/[C II] flux ratio at high-$z$. Note that there are many other AGNs in nearby galaxies (e.g., Graciá-Carpio et al. 2011) and also in a few high-$z$ galaxies (Ferkhioff et al. 2011). Although there are attempts to infer the [N II] 205 $\mu$m flux from the [N II] 122 $\mu$m emission (e.g., Decarli et al. 2012), this method may introduce a large systematic error because the flux ratio of [N II] 122 $\mu$m and [N II] 205 $\mu$m varies by a factor of ~10, i.e., it is strongly dependent on the gas density (see Oberst et al. 2006).

To explore the gas metallicity in LESS J0332 more quantitatively, we carried out model calculations using Cloudy (Ferland et al. 1998) version 08.00. Since the [C II] line arises in both H II regions and PDRs, a consistent treatment to connect those two regions is required to investigate the [N II]/[C II] flux ratio. We assumed a pressure-equilibrium gas cloud that is characterized by certain gas densities and ionization parameters at the illuminated face ($n_{\text{HII}}$ and $U_{\text{HII}}$) for each model run. Here we examine gas clouds with $\log n_{\text{HII}} = 1.5$ and 3.0, and $\log U_{\text{HII}} = -3.5$ and $-2.5$, for $Z_{\text{gas}}/Z_{\odot} = 0.05 - 3.0$. Note that the gas density in PDRs is higher than $n_{\text{HII}}$ under.
the pressure-equilibrium assumption. The input continua are the starburst99 constant star-formation model spectra (Leitherer et al. 1999) with an age of 1 Myr and a stellar metallicity equal to the gas metallicity. We did not take AGN effects into account in the models since the expected AGN contribution is small (see Sect. 3.1). The relative chemical composition of gas clouds is scaled from the solar elemental abundance ratios except for nitrogen, which scales as $Z_{\text{gas}}$ at $Z_{\text{gas}} > 0.23 Z_{\odot}$ (see Kewley & Dopita 2002). Orion-type graphite and silicate grains are included. Calculations are stopped at the depth of $A_V = 100$ mag to cover the whole [C II] 158, um emitting regions, following Abel et al. (2005). Note that the resulting [N II]/[C II] flux ratios are not sensitive to the adopted stopping criterion. The calculation details are given in Nagao et al. (2011).

The [N II]/[C II] flux ratio predicted by the model runs are compared with observations in Fig. 3. The models show that the [N II]/[C II] flux ratio increases monotonically with $Z_{\text{gas}}$. The moderate dependences on parameters other than $Z_{\text{gas}}$, such as $n_H^{\text{II}}$ and $U_{\text{HII}}$, prevent us from determining the accurate $Z_{\text{gas}}$ value. The observed [N II]/[C II] flux ratio ($\sim 0.034$) infers $\log(Z_{\text{gas}}/Z_{\odot}) \sim 0.0 \pm 0.3$, i.e., consistent to the solar metallicity. Although the constraint on the gas metallicity is currently fairly loose, by observing additional lines in the future (such as [N II] 122 $\mu$m and [O I] 145 $\mu$m) it will be possible to constrain the gas properties (density and ionization parameter) and therefore determine the gas metallicity much more accurately.

However, we note that the velocity profiles of the [N II] 205 $\mu$m and [C II] 158 $\mu$m emission are different (Fig. 2). In the redder part of the line the [N II]/[C II] flux ratio is significantly lower than that in the bluer part. If the different [N II]/[C II] ratios for different velocities are caused by metallicity variations, this implies that the system is not chemically homogeneous, but probably resulting from a merging systems where gas with different metallicities has not fully mixed yet. More specifically, the redder component with a high [N II]/[C II] flux ratio may be associated with a chemically enriched galaxy that is merging with a metal poor galaxy, associated with the bluer component characterized by the low [N II]/[C II] ratio. To investigate this scenario more quantitatively, we measured the [N II]/[C II] flux ratio on the redder part ($-550$ km s$^{-1}$ $< V < -150$ km s$^{-1}$) and on the bluer part ($-150$ km s$^{-1}$ $< V < -350$ km s$^{-1}$) of the lines, resulting in a flux ratio of 0.086 and 0.020, respectively. These values roughly correspond to the highest and lowest flux ratios seen in nearby galaxies (Fig. 3), which is indicative of solar-supersolar metallicity in the former case and indicative of solar-supersolar metallicity in the latter case. Note that the two distinct [N II] 205 $\mu$m velocity components are seen in another high-z [N II] 205 $\mu$m emitter, HLS J091828.6+514223 (Combes et al. 2012), which may be another example of a chemically homogeneous system at high-z.

The low-metallicity component in LESS J0332 was already identified in our previous work on this SMG, where we argued (based at that time solely on the [C II] 158 $\mu$m, FIR and CO properties) that the gas metallicity in LESS J0332 is low (De Breuck et al. 2011). However, the most interesting result obtained here is that this system does also host a significant metal-rich component (with solar-supersolar metallicity), indicating that this system is chemically highly evolved already at $z = 4.76$ (the cosmic age of 1.27 Gyr).

This result is consistent with past metallicity studies on high-z AGNs. The diagnostic flux ratios of some UV metallic permitted lines of type-1 quasars show no redshift evolution of the quasar broad-line region up to $z > 6$ (e.g., Nagao et al. 2006c; Juarez et al. 2009). The metallicity in narrow-line regions of type-2 AGNs (which trace larger spatial scales and are therefore more closely related to the host galaxy properties than to the broad-line region) also show no redshift evolution (e.g., Nagao et al. 2006b) even up to $z \sim 5.2$ (Matsuoka et al. 2011). Note that the high-z AGNs investigated in those studies are hosted mostly by massive galaxies (see, e.g., Seymour et al. 2007), similar to SMGs (e.g., Borys et al. 2005). These results on the metallicity of AGNs and LESS J0332 suggest that the chemical evolution of massive systems has progressed very rapidly in the early epoch, $z > 5$, which is qualitatively consistent with the so-called downsizing evolution scenario in galaxies and AGNs (e.g., De Lucia et al. 2006; Ikeda et al. 2011).
