Introduction. The classical goal of control is to force a given system to show robustly a behavior a-priori chosen by the engineer (say, track a desired trajectory). However, feedback control can also be an analysis tool in the given system to show robustly a behavior a-priori chosen by the engineer (say, track a desired trajectory). How-ever, feedback control can also be an analysis tool in the following sense: (i) $u(t) \to 0$ for $t \to \infty$: the time average of the control input tends to zero over time intervals of increasing length. (ii) $u \to 0$ for $N \to \infty$: the control becomes small for an increasing number of particles. The limit $N \to \infty$ has been studied in detail for chimera states. Chimera states are stationary solutions of a well-understood continuum limit system [6–8]. This enables us to compare the chaotic saddle in the finite oscillator system with the corresponding saddle equilibrium in the continuum limit system. However, our control method does not depend on the knowledge of such a limit and it may be useful in general to numerically detect a tipping point of a macroscopic state with an irregular motion on a microscopic level. On the other hand, we will show that the proposed control scheme also works for small system size, where the continuum limit provides only a rough qualitative description.

Applying the control scheme permits us to study the macroscopic state in regions of the phase and parameter space that are inaccessible in conventional simulations or experiments. In the coupled oscillator system this reveals several interesting properties of the stabi-

We present a control scheme that is able to find and stabilize an unstable chaotic regime in a system with a large number of interacting particles. This allows us to track a high dimensional chaotic attractor through a bifurcation where it loses its attractivity. Similar to classical delayed feedback control, the scheme is non-invasive, however, only in an appropriately relaxed sense considering the chaotic regime as a statistical equilibrium displaying random fluctuations as a finite size effect. We demonstrate the control scheme for so-called chimera states, which are coherence-incoherence patterns in coupled oscillator systems. The control makes chimera states observable close to coherence, for small numbers of oscillators, and for random initial conditions.

FIG. 1: (color online) Chimera states far away from complete coherence (a) and close to coherence (b), obtained by numerical simulation of (1), (2) with $A = 0.9$. Upper panels: Snapshot of phases (black) and time-averaged phase velocities (gray). Lower panels: Space-time plots of angular velocities.

We require feedback control (6) to observe pattern (b).
lized chimera states. In the controlled system, we observe a stable branch of chimera states bifurcating from the completely coherent (synchronized) solution. This represents a new mechanism for the emergence of a self-organized pattern from a spatially homogeneous state. We will show that the dynamical regime of the chimera state close to complete coherence can be described as a state of self-modulated excitability. Moreover, it turns out that also the chimera states on the primarily stable branch change their stability properties under the influence of the control. It is known that in the uncontrolled system the chimera states have a dormant instability that will lead eventually to a sudden collapse of the pattern [9]. We will show that this collapse can be successfully suppressed by the control. Since the chimera’s life-span as a chaotic super-transient [10] increases exponentially with the system size, this collapse suppression provides stable chimera states also for very small system size. In addition to the collapse suppression, the control enlarges the basin of attraction such that random initial conditions converge almost surely to the chimera state, which is of particular importance for experimental realizations [11–15].

**Chimera states in coupled oscillator systems.** A chimera state is a regime of spatially extended chaos [16] that can be observed in large systems of oscillators [17, 18] with non-local coupling. It has the peculiarity that the chaotic motion of incoherently rotating oscillators is confined to a certain region by a self-organized process of pattern formation whereas other oscillators oscillate in a phase-locked coherent manner (see Fig. 1(a)). The prototypical model of coupled phase oscillators has the form

\[
\frac{d\theta_k}{dt} = \omega - \frac{2\pi}{N} \sum_{j=1}^{N} G_{kj} \sin(\theta_k - \theta_j + \alpha), \quad k = 1 \ldots N
\]  

where the coupling matrix \( G \) determines the spatial arrangement of the oscillators. Well-studied cases are rings [7, 9, 16–20], two-tori [21, 22] and the plane [23, 24]. We choose here a ring of oscillators and

\[
G_{kj} = G(x_k - x_j) = \frac{1}{2\pi} [1 + A \cos(x_k - x_j)],
\]

where \( x_k = 2k\pi/N - \pi \) is the location of oscillator \( k \) on the ring and \( \theta_k \in [0, 2\pi) \) is its phase. Considering \( x \) as a continuous spatial variable, one can derive the continuum limit equation

\[
\frac{dz}{dt} = i\omega z + \frac{1}{2} e^{-i\alpha} G z - \frac{1}{2} e^{i\alpha} z^2 G z
\]  

for the complex local order parameter \( z(x,t) \), see [6–8] for details. The non-local coupling is here given by the integral convolution

\[
(G\varphi)(x) := \int_{-\pi}^{\pi} G(x - y)\varphi(y)dy.
\]

In this limit a chimera state is represented by a uniformly rotating solution of the form

\[
z(x, t) = a(x)e^{i\Omega t},
\]

where \( \Omega \) is a constant frequency and \( a(x) \) is a time-independent non-uniform spatial profile including coherent regions characterized by \( |a(x)| = 1 \) and incoherent regions where \( |a(x)| < 1 \), see e.g. [8].

A chimera state with finite \( N \) shows temporal and spatial fluctuations around the corresponding stationary limiting profile. The color/shade patterns in Fig. 2(a) show the stationary densities of the global order parameter

\[
r(t) = \frac{1}{N} \left| \sum_{k=1}^{N} e^{i\theta_k(t)} \right|
\]

fluctuating around its mean value for a series of chimera trajectories with varying parameter \( \alpha \). For the continuum limit (3) we obtain a continuous branch of chimera solutions (4) shown as a blue curve in Fig. 2, using the continuum version

\[
r(t) = \frac{1}{2\pi} \left| \int_{-\pi}^{\pi} z(x, t)dx \right|
\]

for the global order parameter, which is constant for a chimera state (4). As Fig. 2(a) shows, the chimera

---

**FIG. 2:** (color online) Chimera states projected to the \((\alpha, r)\) plane (\(N = 400, A = 0.9\)). Panel (a): Uncontrolled chimeras; sequence of simulation runs with stepwise decreasing parameter \( \alpha \). Panel (b): Controlled chimeras; sequence of simulation runs with stepwise increasing control gain \( K \). Blue curve: numerically computed chimera solution of the continuum limit (solid: stable; dashed: unstable). Color/shade patterns: observed density in each run (darker=higher density, see also histograms in Fig. 3). Highlighted runs along dashed lines correspond to the parameter values used in Fig. 1 and Fig. 3. Inset: spectra of the linearized continuum limit (7) for corresponding unstable (a) and stabilized (b) chimera state, marked at \((\alpha, r) = (\pi/2 - 0.1, 0.98)\).
state disappears if one decreases the parameter $\alpha$ beyond $\pi/2 - 0.22$. In the context of the continuum limit $N \to \infty$ this corresponds to a classical fold of the solution branch, which continues as an unstable solution up to the completely coherent state at $(\alpha = \pi/2, r = 1)$.

Control scheme. In order to study this unstable branch in more detail for moderately sized $N$ without relying on the continuum limit, we employ the proportional control scheme

$$\alpha(t) = \alpha_0 + K(r(t) - r_0),$$

where the reference point $(\alpha_0, r_0)$ and the control gain $K$ determine a straight line in the $(\alpha, r)$-plane along which the controlled system evolves in time (see dashed lines in Fig. 2). Setting $K = 0$ corresponds to a vertical line, $K \to \infty$ to a horizontal line. In Fig. 2(b) we show a sequence of stationary densities for chimera states in the plane $\pi/2 - \alpha$ vs. global order parameter $r$, obtained from numerical simulations of (1), now with control (6), increasing the control gain $K$ in steps. The reference point has been fixed to $(\alpha_0, r_0) = (\pi/2 + 0.01, 1)$. In this way, we find stabilized chimera states along the whole branch of equilibria from the continuum limit. Fig. 3 shows in more detail the invasiveness of the control for the runs highlighted in Figs. 2(a) and 2(b) by the dashed lines. Whereas for the uncontrolled run the global order parameter $r$ fluctuates around its equilibrium value from the continuum limit (Fig. 3(a)), in the controlled run both $r$ and $\alpha$ fluctuate around their mean values (Figs. 3(b) and (c)). These fluctuations decrease for an increasing number of oscillators (compare histograms for $N = 100$ and $N = 400$ in Fig. 3). Since for a finite $N$ system the invasiveness of the control is given by the fluctuations of these global quantities, it is non-invasive on average satisfying conditions (i)–(ii) stated above.

Note that chimera states in a system with a nonlinear state-dependent phase-lag parameter have been investigated already in [25]. However, the feedback in [25] depends on the local order parameter such that it cannot be interpreted as a global non-invasive control of the original system in the sense of [5]. Proportional control (6) is only one option to achieve non-invasive control on average for a chaotic saddle in the relaxed sense of conditions (i)–(ii). Alternatives are any non-invasive methods for stabilization of unknown equilibria. For example, a PI (proportional-integral) control was used in [26] to explore the saddle-type branch of a partially synchronized regime in a small-world network in the continuum limit. Time-delayed feedback or wash-out filters [27] are suitable near instabilities other than folds of the continuum-limit equilibrium; for instance in [28], time-delayed feedback has been used to suppress or enhance synchronization in a system of globally coupled oscillators.

Spectral stability analysis. In the continuum limit (3), the control (6), (5) acts in an exactly non-invasive manner and the stabilization can be shown as follows. For a solution (4) with $\alpha = \alpha_*$ and $r = r_*$, we insert

$$z(x, t) = (a(x) + v(x, t))e^{i\sigma t}$$

into Eq. (3) with control (6), (5) and linearize the result with respect to the small perturbation $v$. As a result, we obtain the linear equation (c.f. [16])

$$\frac{dv}{dt} = \mathcal{L}v := \eta(x)v(x, t) + \mathcal{K}v + \mathcal{C}v,$$  

(7)

containing the multiplication operator

$$\eta(x) := i(\omega - \Omega) - e^{i\alpha}a(x)G\pi$$

(8)

and the compact integral operators

$$(\mathcal{K}v)(x) := \frac{1}{2}e^{-i\alpha}Gv - \frac{1}{2}e^{i\alpha}a^2(x)G\pi,$$

$$(\mathcal{C}v)(x) := \frac{iKa(x)^2}{4\pi^2 r_s} \Re \left( \int_{-\pi}^{\pi} \pi(y)dy \int_{-\pi}^{\pi} v(y)dy \right),$$

where $\mathcal{C}v$ accounts for the action of the control. Spectral theory for this type of operators (see [8] for details) implies that the spectrum $\sigma(\mathcal{L})$ consists of two qualitatively different parts: (i) essential spectrum

$$\sigma_{\text{ess}}(\mathcal{L}) = \{ \eta(x) : -\pi \leq x \leq \pi \} \cup \{c.c.,$$

which for partially coherent states is known to have a neutral part [29]; (ii) point spectrum $\sigma_{\text{pt}}(\mathcal{L})$ consisting of all isolated eigenvalues of the operator $\mathcal{L}$. For the chimera states shown in Fig. 2, the point spectrum contains at most one real eigenvalue, which determines their stability. This eigenvalue can be found by inserting $v = v_0(x)e^{i\lambda t}$ into Eq. (7),

$$v_0(x) = (\lambda - \eta(x))^{-1}(\mathcal{K}v_0(x) + \mathcal{C}v_0(x)).$$

(9)
Applying now the integral operator \( K + C \) to both sides of Eq. (9) we arrive at a spectral problem for \( w := (K + C)v_0 \)
\[
w = (K + C) \left( (\lambda - \eta(x))^{-1} w \right). \tag{10}
\]
As pointed out in [18], the operators \( G \) and \( K \) have finite rank for the coupling function (2) (the control term \( C \) has always rank one). Therefore, expanding \( w \) as a Fourier series and projecting Eq. (10) onto the first three modes \( f_1(x) = 1, f_2(x) = \cos x, f_3(x) = \sin x \), we obtain a closed linear system
\[
\dot{w}_k = \frac{1}{\pi} \int_{-\pi}^{\pi} f_k(x)(K + C) \left( (\lambda - \eta(x))^{-1} w \right) dx \tag{11}
\]
for the unknown Fourier coefficients \( \hat{w}_0, \hat{w}_1 \) and \( \hat{w}_2 \). Its determinant gives an equation that is nonlinear for the real eigenvalues \( \lambda \) and linear in the gain \( K \). The insets in Fig. 2 show the spectra calculated in this way, indicating the unstable eigenvalue in panel (a), which disappears due to the control (b).

**Suppression of collapse and enlarged basins.** We study now the influence of the control scheme on the classical chimera states far from complete coherence, which are already stable without the control (solid blue curve in Fig.2(a)). As described in [9], the classical chimera states from time to time show a sudden transition to the stable completely coherent state and have to be considered as weakly chaotic type-II supertransients [10]. The life-time before collapse increases exponentially with the system size which implies that chimera states disappear quickly for \( N \approx 20 \) (cf. Fig. 4(a)), whereas they typically appear as stable objects for any observable time-span if \( N > 100 \). The collapse process can be understood as follows. Driven by finite size fluctuations, the trajectory can tunnel through the barrier represented by the chimera on the unstable branch and eventually reach the stable coherent state. Applying the control, this scenario changes drastically: Increasing the control gain \( K \), the mean life-time before collapse increases by several orders of magnitude and, at the same time, the basin of attraction of the chimera state grows correspondingly. Fig. 4(c) shows the average observed life-times for increasing values of \( K \). In our simulations over \( 10^5 \) time units, which we performed for each \( K \), the number of observed collapses decreased successively until for \( K > 0.5 \), we did not observe a single collapse event during this time span. Finally, for \( K \geq K_c \approx 0.67 \) the chaotic saddle acting as a barrier disappears and the completely coherent state becomes unstable, which ultimately prevents a collapse to this state. Accordingly, all random initial data converged to the chimera state. Note that we have chosen the reference point on the chimera branch, see Fig. 4(b), such that the given chimera state exists for all values of the control gain \( K \). Hence, with feedback control stable chimera states can be observed for considerably smaller values of \( N \), and arbitrary initial conditions, which is of particular importance for experimental realizations.

**Self-modulated excitability close to coherence.** Up to now, stable chimera states have been observed only far from the completely coherent solution, except for the results in [30] where the onset of incoherence has been triggered by an inhomogeneous stimulation profile. In the controlled system (1), (6) there is a stable branch of chimera states bifurcating from complete coherence. This is another example of a pattern forming bifurcation mechanism in a homogeneous system with a diffusion like coupling that should in principle stabilize homogeneity.

The chimera states close to complete coherence display particular properties distinguishing them from classical chimera states. Fig. 4(b) shows that the onset of incoherence manifests itself as the emergence of isolated excitation bursts caused by phase slips of single or few oscillators, which appear irregular in space and time but are confined by a process of self-localization to a certain region. Indeed, close to the bifurcation point the dynamics of each single oscillator is close to a saddle-node-on-limit-cycle bifurcation. Hence, the emergence of a chimera state can be understood as a transition from quiescent to oscillatory behavior, which happens in a self-localized excitation region within a discrete excitable medium. At the same time, the isolated phase slipping events are not well described by the average quantities from the continuum limit, which are continuous in space and constant in time.

**Conclusion.** We demonstrate that a feedback control that is non-invasive in our relaxed sense is useful for
exploring complex dynamical regimes in large coupled systems. In particular, it can be used to classify the disappearance of a chaotic attractor as a transition to a chaotic saddle, which is the classical scenario for so-called tipping, e.g., in climate [31], without relying on a closed-form continuum limit. Specific to partial coherence, feedback control is feasible and useful in existing experimental setups of coupled oscillators [12–15] as the coupling in these experiments is computer controlled or through a mechanical spring. Feedback control makes it possible to study the phenomenon of partial coherence for much smaller $N$, close to complete coherence, and without specially prepared initial conditions.
