**INTRODUCTION**

The human gut microbiome is composed of trillions of microorganisms including bacteria, fungi, viruses and archaea, which co-exist in a balanced relationship with their host in healthy state. Among others, the microbiome protects against pathogens, modulates the immune system and regulates endogenous metabolism of nutrients, in concert with lifestyle-related factors. The advent of microbial DNA sequencing technologies has allowed profiling of diverse microbial communities in the gut, providing evidence that although its composition displays huge inter-individual variation, there is a common pattern. The human gut microbiota is composed of more than 1000 different microbial species with particular taxonomic characteristics. The prevailing phyla composing the usual gut microbiota are *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, *Proteobacteria*, *Fusobacteria* and *Verrucomicrobia*, with the two first corresponding
90% of gut microbiota. Although gut microbiota composition is considered generally stable at short-term, fluctuations and acute changes may occur both at short- and long-term after exposition to disruptive factors such as diet, medication, ageing and pathological conditions.

Emerging evidence implicates alterations in gut microbiota (ie gut dysbiosis) to play a central role in the pathogenesis of many diseases including chronic kidney disease (CKD). CKD is a noteworthy global public health issue with rising prevalence that affects over 850 million individuals worldwide. Common causes of CKD include diabetes, hypertension, glomerulopathies, tubulo-interstitial nephritis secondary to infections or exposure to nephrotoxic agents, among others. As kidney function declines, CKD is characterized by metabolic complications including anaemia, metabolic acidosis and abnormalities in bone and mineral metabolism. Abnormalities in bone and mineral metabolism not only lead to an increased risk of fractures, but have also been associated with an increased risk of vascular calcification, cardiovascular complications and mortality. Uraemia also promotes an imbalance in the intestinal microbiota, resulting in an increased production of toxins and deleterious effects, such as vascular and renal disease progression.

Although vascular calcification and bone disorders in CKD patients are generally considered to be driven by shared pathophysiological mechanisms, it has only recently been appreciated that gut microbiota may be a major third component influencing both vasculature and bone. This review aims to describe emerging evidence on abnormalities in the vascular system, bone, and gut and their interrelationship termed the ‘gut-bone-vascular axis’ in progressive CKD.

2 | VASCULAR AND BONE ABNORMALITIES IN CKD

2.1 | Vascular calcification

Along with the decline in GFR, a systemic change in mineral metabolism takes place in patients with progressive CKD. These changes are collectively termed Chronic Kidney Disease-Mineral and Bone Disorder (CKD-MBD). CKD-MBD is characterized by one or more abnormalities in circulating minerals or their regulating hormones (eg calcium, phosphorus, PTH and vitamin D), bone abnormalities and vascular calcification.

Chronic kidney disease is accompanied by an excessively high cardiovascular mortality risk, which may be at least in part be attributed to vascular calcification in the context of CKD-MBD. Extensive deregulations in bone and mineral metabolism may be observed even in very young dialysis patients and contribute to detrimental outcomes. Vascular calcification is an active and highly regulated cellular process, defined by the deposition of calcium-phosphate crystals within the intima and media layers of the vasculature and/or heart valves. Besides well-known traditional risk factors for vascular calcification such as age, male gender, diabetes, dyslipidaemia, hypertension, smoking and inflammation, vascular calcification in CKD patients (since early stages until after renal replacement therapies) is additionally driven by deregulations in mineral metabolism, and phenotypic changes in vascular smooth muscle cells (VSMC) represent the initial step in this pathological process, namely osteochondrogenic differentiation and apoptosis of VSMC. Multifaceted intricate mechanisms in CKD-induced vascular calcification also comprise the instability and liberation of matrix extracellular vesicles containing calcium and phosphate from bone and VSMC, and elastin (most abundant protein in media wall) degradation, promoting calcium deposition.

Moreover, an unbalanced environment brought by the mineral deregulations impairs the effects of vascular calcification inhibitors (eg pyrophosphate, adenosine, matrix Gla protein, osteopontin, fetuin-A, osteoprotegerin, bone morphogenetic protein-7, magnesium, vitamin K, klotho), while enhancing the action of promoters (eg inflammatory cytokines, oxidative stress, uremic toxins, osteocalcin, osteonectin, bone morphogenetic protein-2, Runx2, secondary calciprotein particles). Deregulations in many of these factors have been identified and linked with vascular calcification and adverse clinical outcomes. A recent study with CKD patients with different levels of renal function has demonstrated an augmented expression of alkaline phosphatase and Runx2 in VSMC of CKD arteries, an indicative of osteogenic differentiation. The role of Wnt inhibitors such as sclerostin and DKK1 (dickkopf-1) remains controversial. Interestingly, many of the above-mentioned factors are not only involved in vascular calcification, but also regulate bone metabolism, and are implicated in bone abnormalities in CKD.

2.2 | Bone disease in chronic kidney disease

Chronic kidney disease is characterized by a strongly elevated fracture risk, with dialysis patients exhibiting a risk ranging from 1.5 to 8-fold in comparison with the general population. Between 1992 and 2009, there has been an increase of 50.2% in the incidence of hip and vertebral fractures and of 40.6% in arm and leg fractures requiring hospitalization among haemodialysis patients in the United States. A more recent epidemiological study has disclosed an inverse association between estimated glomerular filtration rate (eGFR) and fracture incidence with a hazard ratio of 1.25 (95% CI 1.05-1.49) for eGFR <60 mL/min/1.73 m² and 1.65 (95% CI 1.14-2.37) for eGFR <45 mL/min/1.73 m². Furthermore, the effect of decreased eGFR on fracture incidence was more noticeable in younger and male patients.
Moreover, haemodialysis patients presenting with a fracture had higher unadjusted rates of death (3.7-fold) and death/rehospitalization (4.0-fold) dialysis patients without a fracture. The increased risk of fracture has also been observed among CKD patients after kidney transplantation. Over the first 3 years following transplantation, the risk of a hip fracture is 34% higher than in dialysis patients, and over the first 5 years post-transplant one-fourth will have a fracture. A recent meta-analysis has disclosed an overall fracture incidence rate of 8.95 per 1,000 person-years among dialysis patients and kidney transplant recipients (KTR).

2.3 Vascular calcification and bone disease in CKD: Shared aetiology?

The parallel development of bone disease and vascular calcification in CKD patients and the overlapping factors driving these deregulations implicate a shared aetiology, at least in part. A large body of evidence has already documented the coexistence of bone disease and vascular calcification in CKD patients. Nevertheless, the mechanisms connecting abnormalities in bone and vasculature remain incompletely understood. Since bone matrix is rich in regulatory factors that are also active in the vasculature, such as osteopontin and MGP, they may be released into the circulation during bone resorption. Cells with both osteoblastic and osteoclastic potential have been described in vascular tissues, and bone-related proteins have been identified in calcified arterial lesions. Alternatively, causal factors driving both vascular calcification and bone loss in CKD may exist, supported by the several risk factors common in both disorders, including vitamin K and D abnormalities, chronic inflammation, dyslipidaemia, ageing, hyperparathyroidism, hyperhomocysteinaemia, oestrogen deficiency and oxidative stress. As discussed in the 2006 KDIGO guidelines, the term CKD-MBD should not solely be used to describe the syndrome of biochemical and bone abnormalities observed in CKD, but also encompasses the extra-skeletal calcification occurring in these patients resulting from derangement of complex systems biology involving the kidney, skeleton and cardiovascular system.

Although a causal relationship has not been conclusively established, CKD-MBD, and particularly hyperphosphataemia, represents one of the major triggers for vascular calcification. Hyperphosphataemia stimulates both PTH and fibroblast growth factor-23 (FGF23) synthesis, subsequently inducing phosphaturia through an effect on type II renal sodium-dependent phosphate transporters. However, abnormal levels of PTH and FGF23 may be associated with vascular calcification even before the development of hyperphosphataemia. High levels of PTH and FGF23 in CKD promote bone resorption, which may further increase serum calcium-phosphate product in a vicious circle. When vascular smooth muscle cells (VSMC) are exposed to a calcium and phosphorus-rich environment they undergo osteogenic differentiation becoming bone-formative cells, namely osteoblast/chondrocyte-like cells. These cells lose their contractile properties but produce a collagen matrix and form calcium- and phosphorus-rich matrix vesicles, which in turn may initiate the mineralization of the vascular wall.

At the same time, a dynamic bone disease, characterized by markedly reduced bone formation rate and low PTH (low bone remodelling), may also be associated with ectopic calcification of vessels valves and heart. It seems that osteo-chondrogenic differentiation of VSMC depends on higher expression of type III sodium-dependent phosphate transporters (Pit-1 and Pit-2) hence contributing to vascular calcification in CKD-MBD. There is experimental evidence that Klotho, a co-receptor relevant for canonical FGF23 signalling, confers anti-calcification effects by inducing phosphaturia, preserving GFR and even through a direct effect on soft tissues including the vascular smooth muscle. Thus, deregulations in bone and mineral metabolism may induce both bone disease and vascular calcification in CKD. At the same time, additional factors such as chronic inflammation, which is common in CKD, and also loss of Klotho may adversely affect both bone and vasculature.

2.4 Inflammation: Driving bone disease and calcification in CKD?

In CKD, the presence of so-called uremic micro-inflammation has been recognized as an essential pathophysiological constituent, that plays an important role as a contributor to both vascular calcification and bone disease. A large cohort study has disclosed that biomarkers of inflammation such as IL-1β (interleukin 1 beta), IL-6 (interleukin 6) and TNF-α (tumour necrosis factor alpha) were inversely associated with eGFR (estimated glomerular filtration rate) and cystatin-C and positively with albuminuria, indicating a role for inflammation on CKD development and progression. The mechanisms linking inflammation with vascular calcification are complex and multifactorial. A great amount of inflammatory mediators, such as oxidative stress, carbonyl stress, C-reactive protein and cytokines may directly stimulate vascular calcification. Moreover, inflammation decreases the calcification inhibitor fetuin-A. Importantly, the pro-inflammatory cytokines TNF-α, receptor activator of NF-κB ligand (RANKL) and interleukins 1 and 17 also have adverse effects on bone. TNF exerts an effect on osteoclastogenesis by acting directly on osteoclast precursors while IL-6 can upregulate RANKL and thus indirectly support osteoclast formation via the interaction with mesenchymal cells. A histomorphometric study performed by Viaene et al in end-stage kidney disease...
(ESKD) patients showed that inflammatory markers IL-6 and TNF-α were independently associated, respectively, with aortic calcification and low bone area, emphasizing the role of micro-inflammation in the bone-vascular axis in CKD. The source of chronic inflammation remains unclear in many CKD patients, and its aetiology may be multifactorial. Accumulating evidence points towards the gastrointestinal tract as a major source of inflammation in CKD.48

3 | GUT MICROBIOTA IN CHRONIC KIDNEY DISEASE

Experimental and clinical evidence points towards a distinct intestinal microflora composition in CKD.4 It is well known that a healthy, balanced colonic microbiota is primarily composed of saccharolytic bacteria (ie carbohydrates fermenting bacteria).3 In the context of a reduced GFR, the intestine is exposed to uraemia. The prolonged exposure to high concentrations of urea causes overgrowth in urease containing bacterial families,49 accounting for greater ammonia generation and further increased intestinal pH. Moreover, in ESKD, there is also an increased concentration of uric acid and oxalate secretion in the gastrointestinal (GI) tract since colon becomes their main route of excretion,4 accounting for an increasing abundance of uricase producing microbes.49 The aforementioned increased proliferation of proteolytic bacterial species (ie uricase and urease containing species) confers gut dysbiosis in CKD. A recent systematic review showed that patients in any stage of CKD, ranging from early GFR decline to end-stage kidney disease, presented with substantial differences in gut microbiota composition, compared to healthy individuals.50 However, some differences in microbiota composition within the CKD population can also be discerned. In early CKD, some beneficial microbial families such as Ruminococcaceae and Lachnospiraceae, which are enriched in the general population and capable of degrading polysaccharides, were observed.50 In advanced CKD, families associated with the production of uremic toxins are considerably more common, whereas families linked with production of SCFAs are markedly reduced.50 These findings suggest that the microbiota in early CKD may be closer to healthy individuals, whereas in advanced CKD dysbiosis is more common.

Gut dysbiosis promoted by the uraemic milieu also accounts for the loss of gut barrier integrity, which in turn allows the translocation of living bacteria, endotoxin molecules (lipopolysaccharides), and gut-derived uremic toxins into the systemic circulation.51 The increased exposure of the host to these components may activate innate immunity and systemic inflammation, increasing the ratio of the intestinal T helper 17 (Th17) cells over T regulatory (Treg) cells, creating a vicious circle.52,53 Moreover, the aforementioned proteolytic bacterial species amplified in CKD produce uraemic toxins generated through protein fermentation in the intestine,54 including p-cresyl sulphate (P-CS), indoxyl sulphate (IS) and trimethylamine N-oxide (TMAO),54 all of which have pro-inflammatory effects.54 Alterations in microbiota composition also comprise the depletion of protective microbial species including the ones capable of producing anti-inflammatory and cytoprotective molecules such as short-chain fatty acids (SCFA).49

In addition to uraemia, other aspects that further contribute to the changes in gut microbiota composition in CKD patients include diet and medications.55 Protein restriction is a major component of the ‘renal diet’, which not only aims to preserve renal function, but also to reduce uremic toxin production.55 Moreover, in order to avoid hyperkalemia and oxalate overload, dietary recommendations include limiting the consumption of fruits and vegetables, food groups that are also rich in fibre, hence interfering with symbiosis in GI tract.56 Instead of focussing on specific nutrients, some authors have investigated the potential role of healthy dietary patterns, such as vegetarian and Mediterranean diet, upon gut microbiota composition in CKD.57,58 A cross-sectional study has disclosed that vegetarian haemodialysis patients presented lower levels of IS and P-CS when compared to omnivorous patients.57 The higher fibre and reduced amount of animal protein of a vegetarian diet may account for such beneficial effects. The Mediterranean diet is characterized by providing a favourable ratio of protein-to-carbohydrate intake for gut microbiota, since it is mainly composed of whole grains, nuts, fruits and vegetables, with modest intake of fish and dairy products and low intake of red meat. Although this dietary pattern did not reduce uraemic toxin production in CKD patients,58 it was able to increase healthy gut microbiota constituents and SCFA production in healthy subjects.55 Chronic intestinal constipation, another frequent condition in CKD, might also influence the intestinal microflora.59,60

Chronic kidney disease and its frequent comorbidities leads to polypharmacy (defined as the continuous use of five or more medications per day) in 80% of patients, of whom 20% use >10 different medications per day.61 Many drugs have documented impact on gut microbiota composition.62-69 For example, phosphate binders can affect gut microbiota by impairing vitamin and phosphate absorption.62 Besides affecting microbiota, calcium-based phosphate binders may further increase the risk of extra-skeletal calcifications by inducing a rise in serum calcium levels or reducing intestinal absorption of vitamin K2.62 A recent review has reported adverse effects of oral iron supplementation on gut microbiota composition, gut metabolome and intestinal health, which in turn may result in increased production of uremic toxins in CKD.64 The frequent use of antibiotics by CKD patients does not only impact the target pathogen but also commensal gut bacteria.63 Proton-pump inhibitors (PPI), another class of
medications commonly used by CKD patients, have been associated with important changes in gut microbiome because of long-term reduction of gastric acid secretion and hypochlorhydria. Finally, immunosuppression therapy after kidney transplantation can induce profound alterations in gut microbiota composition.

Interestingly, deregulations in gut microbiota may contribute to vascular and bone disease in CKD patients (the ‘gut-vascular-bone axis’), among others through a metabolic shift from a predominant saccharolytic to a proteolytic fermentation pattern, an altered intestinal barrier function and impaired vitamin K status.

4 | GUT-VASCULAR-BONE AXIS IN CKD

Several factors may connect gut abnormalities with vascular calcification and bone disease in CKD patients; these include uraemic toxins, TMAO, vitamin K and SCFA.

4.1 | Uremic toxins

The uremic toxins P-CS and IS originate from intestinal microbial metabolism of tyrosine/phenylalanine and tryptophan, respectively. After absorption by colonic mucosa, these compounds are conjugated with sulphate in the liver to IS and P-CS, which are either bound to albumin or circulate in free forms. In CKD, the augmented microbial production and increased intestinal permeability both contribute to progressive accumulation of serum uremic toxins. Conventional haemodialysis is not able to efficiently remove IS due to its high binding affinity to albumin in plasma. Higher levels of both P-CS and IS are associated with accelerated CKD progression and cardiovascular disease.

In CKD patients, plasma IS concentrations can be 100-fold higher than healthy individuals. This disproportionate amount of plasmatic uremic toxins prompts the production of free radicals in both renal cells and VSMC through oxidative stress and inflammation, causing tissue injury. IS induces the expression of osteoblast-specific proteins and aortic wall calcification and thickening in Dahl salt-sensitive hypertensive rats. In line, IS has been shown to promote a phenotypic switch of vascular smooth muscular cells (VSMC) from a contractile to an osteogenic phenotype. An experimental study has demonstrated that a concentration of IS comparable to that observed in ESKD patients was able to cause VSMC proliferation in rats. In vitro, P-CS may act as a pro-osteogenic and procalcific toxin. In a more recent elegant in vivo study, long-term exposure to IS and P-CS significantly increased calcification of the aorta and peripheral arteries of CKD rats. Jing et al demonstrated that serum P-CS triggers monocyte-endothelial cell interaction in vitro through increased production of reactive oxygen species. Additionally, in vivo, increased P-CS levels promoted atherogenesis in 5/6-nephrectomized apoEL/L mice, compared with controls. Moreover, the observed activation of inflammation and coagulation signalling pathways in aorta preceding the calcification, implicated these signalling pathways in toxin-induced arterial calcification.

Only a handful of clinical studies have investigated the association between uremic toxins and vascular calcification in CKD. Barreto et al have disclosed a positive association between IS serum levels and pulse wave velocity and aortic calcification in different stages of CKD, with IS being a powerful predictor of overall and cardiovascular mortality. Subsequently, the same group demonstrated an association between P-CS and vascular calcification in CKD patients, suggesting P-CS levels as predictors of overall and cardiovascular death. Rossi et al found progressively increased levels of total and free serum IS and P-CS in more advanced stages of CKD. Furthermore, total and free serum IS and P-CS were independently associated with structural and functional markers of cardiovascular disease, such as carotid intima-media thickness (cIMT), and endothelial function. Among haemodialysis (HD) patients, PC-S levels were associated with high carotid-femoral pulse wave velocity (PWV) and seemed to be predictors of higher arterial stiffness in ESKD. In line, a study in HD patients demonstrated increased levels of serum P-CS in patients with carotid atherosclerotic plaque (CAP), and reported a positive correlation with higher total plaque area. Moreover, P-CS levels were independently associated with the incidence and progression of CAP, and promoted induction of inflammatory factors and adhesion molecule expression in endothelial cells and macrophages. Finally, a large cohort study of children with CKD also found significant associations between a higher IS level and higher cIMT and progression of PWV, independent of other risk factors. It is worth mentioning that all these data derive from observational studies, requiring further confirmation in prospective intervention studies in humans.

Although little is known on the effects of uraemic toxins on bone health in CKD patients, emerging evidence indicates that IS may inhibit osteoclast differentiation and PTH signalling. Moreover, several in vitro studies have disclosed that IS jeopardizes the differentiation of mesenchymal stem cells to osteoblasts, inhibit osteoblast proliferation, bone mineralization, alkaline phosphatase activity and expression of bone formation-related genes. A study in parathyroidectomized rats demonstrated that IS-induced low bone turnover may be due to mechanisms unrelated to skeletal resistance to PTH. Treatment of mesenchymal stem cells (MSC) with high concentrations of uremic toxins, namely P-CS or IS, during osteogenic differentiation promoted down-regulation of collagen type I, reduction...
in alkaline phosphatase activity and impairment of MSC mineralization. These results reinforce that uraemic toxins negatively influence osteogenesis. The resistance to PTH effects on bone in CKD setting is well recognized, although the underlying mechanisms have not been fully elucidated yet. In line, Nii-Kono et al demonstrated that higher serum IS promotes PTH resistance in osteoblasts. In an experimental model of CKD, IS and other uremic toxins changed bone composition. In haemodialysis patients, IS was inversely correlated with alkaline phosphatase and bone-specific alkaline phosphatase, irrespective of intact PTH, suggesting that IS may be implicated in skeletal PTH resistance in uraemia. Furthermore, increased levels of IS prompt 24-hydroxylase (CYP24A1) activity, causing 25-hydroxyvitamin D and active vitamin D degradation, thereby reducing calcitriol (1,25-dihydroxycholecalciferol) levels.

Altogether, these findings suggest that patients with CKD may develop low-turnover bone disease by a direct action of IS on both osteoblast and osteoclast precursors to suppress bone formation and bone resorption. However, further studies are needed to elucidate the mechanisms of action of uraemic toxins in bone disease progression in uraemia.

### 4.2 Trimethylamine-N-oxide

Trimethylamine N-oxide is derived from metabolization of trimethylamine (TMA)-containing substrates, such as L-carnitine, choline and betaine, by intestinal bacteria. These compounds are found in a variety of foods, including those of animal origin such as red meat, eggs, milk, fish, poultry and shellfish, and those of plant origin, such as green vegetables, whole grains, spinach and beets. Bacterially produced TMA is efficiently absorbed into the circulation and metabolized by the hepatic enzyme flavin monooxygenase to form TMAO.

In previous large clinical studies, high serum levels of TMAO have already been associated with cardiovascular diseases, besides promoting atherosclerosis in rodents. It is well established that CKD patients, with different levels of renal function, have increased production and serum levels of TMAO due to altered gut microbiota and reduced renal function. A recent well-designed study involving haemodialysis patients showed higher TMAO levels in patients with aortic calcification, compared with patients without calcification, and a positive association between serum TMAO and aortic calcification scores. In cultured VSMCs, TMAO promoted calcium/phosphate-induced calcification, and in an animal CKD model, TMAO promoted vascular calcification. Furthermore, reducing TMAO levels by using antibiotics ameliorated vascular calcification in CKD rats. The authors have also demonstrated that TMAO promotes vascular calcification and osteogenic differentiation of VSMCs in the context of CKD via NLRP3 (nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3) and NF-κB (nuclear factor κB) signalling pathways.

Recent studies investigated the role of TMAO in bone health and in age-related osteoporosis and type 2 diabetes, but data in CKD patients are currently lacking. Interestingly, TMAO treatment in vitro promoted adipogenic differentiation and inhibited the osteogenic differentiation of bone marrow mesenchymal stem cells (BMSCs) by up-regulating the NF-κB signalling pathway. Such observations highlight the importance of investigating the role of gut microbiota of CKD patients on serum levels of TMAO and whether it impacts on vascular calcification and bone health.

### 4.3 Vitamin K

Vitamin K, a fat-soluble vitamin, plays a role in bone metabolism and vascular calcification and its deficiency is common in CKD. Subclinical vitamin K deficiency is also observed in CKD patients, further supporting an increased risk of vascular calcification and bone demineralization. It exists in two main forms: vitamin K1 (phyloquinone, PK), synthesized by plants and found in green leafy vegetables; and vitamin K2 (menaquinone-n, MK), mainly synthesized by bacteria, can be found in yogurts and other fermented foods besides being produced by gut microbes. Bacterial MK present in the colon are mainly MK-10 and MK-11, synthesized by Bacteroides, MK-8 by Enterobacteria, MK-7 by Veillonella and MK-6 by Eubacterium lentum. Usually, up to 90% of total vitamin K intake comes from PK, with 10 to 25% deriving from MK. Yet, some authors consider that even small amounts of vitamin K2 derived from intestinal bacteria can have a significant impact on health.

Diets poor in potassium (reduced leafy green vegetables rich in K1) and low in phosphate (reduced dairy products rich in K2) normally prescribed for CKD patients, thus represent a potential cause of vitamin K deficiency. Besides dietary factors and the use of medications such as vitamin K antagonists and phosphate binders, the altered gut microbiota composition in CKD patients may also contribute to worsening of vitamin K deficiency in this population. A recent study in patients with Crohn’s disease has shown a reduction in the diversity of gut bacteria in vitamin K-deficient patients. A well-designed experimental study has shown that mice with disrupted microbiota displayed modified abundance of microbial genes responsible for the synthesis of vitamin K. In addition, the disruption of gut microbiome was associated with decreased crystallinity and impaired
bone tissue strength.\textsuperscript{116} The potential role of gut microbiota composition in relationship with vitamin K status in the CKD setting remains to be addressed.

Vitamin K-dependent proteins (VKDP), including osteocalcin (OC) and matrix Gla-protein (MGP), are important regulators of bone mineralization.\textsuperscript{117} OC is exclusively synthesized by osteoblasts and binds to calcium ions and hydroxyapatite crystals exerting regulatory effects on bone mineral matrix.\textsuperscript{117} MGP is produced by VSMC and chondrocytes to prevent ectopic calcification.\textsuperscript{106,117} Reduced serum levels of carboxylated MGP appear to be a noticeably contributor to the development and progression of vascular calcification.\textsuperscript{118} Furthermore, by stimulating the xenobiotic receptor on osteoblasts, vitamin K can alter bone mineralization processes.\textsuperscript{119} Given that vitamin K is essential to functionalize a series of proteins including OC, the most abundant non-collagenous protein in bone matrix,\textsuperscript{119} the lack of matrix-bound OC in bone turns it more fragile and susceptible to fracture.\textsuperscript{119} Reduced intake of vitamin K and functional vitamin K deficiency, as determined by circulating biomarkers, such as dephosphorylated-uncarboxylated MGP (dp-ucMGP) or undercarboxylated OC (unOC), are associated with low BMD and increased risk of fractures in general population\textsuperscript{120} as well as in CKD patients.\textsuperscript{121} An observational study which evaluated the impact of vitamin K upon vascular calcification and bone health in haemodialysis patients revealed that vitamin K1 deficiency was the strongest predictor of vertebral fractures, while MK4 deficiency was a predictor of aortic calcification and MK7 deficiency a predictor of iliac calcification.\textsuperscript{121} Several studies have found positive associations between vascular calcification and vitamin K deficiency.\textsuperscript{110,122,123} A recent cohort study with ESKD patients has disclosed that dp-ucMGP was strongly associated with coronary artery calcium (CAC) and aortic valve calcium; however, a stepwise regression analysis revealed that dp-ucMGP was not an independent determinant of vascular calcification. At the same time, a randomized clinical trial has shown that 12 months of vitamin K2 supplementation did not improve vascular stiffness in non-dialysis CKD patients, and this was similar in an updated meta-analysis.\textsuperscript{124} These findings suggest a complex and yet un clarified interconnection between vitamin K deficiency, bone disease and vascular calcification. Six randomized clinical trials to investigate the effects of vitamin K supplementation upon vascular calcification in haemodialysis patients are ongoing.\textsuperscript{125}

4.4 | Short-chain fatty acids

Short-chain fatty acids are the products of bacterial fermentation of non-digestible carbohydrates in the colon, such as dietary fibres and resistant starches.\textsuperscript{126} SCFA account for 2 to 10% of the total energy consumption in humans and serve as energy source for the colonic epithelial cells and the microbiota.\textsuperscript{126} The most abundant SCFA are acetate, propionate and butyrate, mainly produced by \textit{Firmicutes} and \textit{Bacteroides}, and rapidly absorbed by the intestinal epithelium through specific transporters or diffusion.\textsuperscript{3,126} The benefits of SCFA are not limited to the intestine, where they are produced,\textsuperscript{127} SCFA seems to contribute to the improvement of vascular phenotypes.\textsuperscript{75} Some studies have shown immunomodulatory capacities of SCFA. Inflammatory cells such as neutrophils, macrophages, dendritic cells and T cells are responsive to SCFA treatment, in line with their anti-inflammatory effects in a wide range of inflammatory diseases, and reduction of vascular calcification,\textsuperscript{128} although studies in this field are still limited.

Recent emerging evidence supports beneficial effects of SCFA on bone health.\textsuperscript{129,130} Mice treated with SCFA for 8 weeks showed significantly increased bone mass and decreased bone resorption.\textsuperscript{129} In the same study, the authors also investigated the influence of a fibre-rich diet, which increased SCFA levels in the cecum and serum, upon bone health,\textsuperscript{129} and concluded that the diet helped to further increase bone mass. Zhou et al\textsuperscript{130} have reported a direct association between dietary fibre consumption and BMD mainly in men and among participants with lower genetically determined gut microbiota-derived SCFA propionate.

As aforementioned, the gut microbiota of CKD patients is characterized by a higher abundance of bacterial species containing proteases compared to species containing enzymes that degrade fibre and generate SCFA,\textsuperscript{39} besides a low fibre intake due to renal dietary restrictions.\textsuperscript{56} Serum butyrate levels were threefold lower in Chinese CKD patients compared to healthy controls.\textsuperscript{131} Moreover, an inverse correlation between butyrate and renal function has been reported.\textsuperscript{151} In contrast, Terpstra et al\textsuperscript{132} could not find a reduction in butyrate-producing species nor in butyrate production capacity in a sample of Dutch CKD patients, although total SCFA was not measured. Thus, although SCFA could be another link in the gut-bone-vascular axis, the relevance in CKD patients deserves further study.

5 | Therapeutic Interventions

Individualized approaches pursuing the re-establishment of a symbiotic status of the gut microbiota in CKD may benefit the gut-vascular-bone axis in CKD, hence helping to mitigate vascular calcification and bone mineral disease. These targets may be accomplished through dietary modifications, mainly by increasing fibre intake, administrating probiotics, prebiotics or symbiotics and through the supplementation of vitamin K, when necessary.
Probiotics are defined by the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO) as 'living organisms that provide health benefits in the host when consumed in the appropriate quantity'. To date, there are no studies that directly investigate the effects of probiotics, prebiotics or symbiotics supplementation upon vascular calcification and bone health in CKD patients. However, a recent randomized controlled trial with non-dialysis CKD patients has shown that a three-month supplementation with fructooligosaccharides (FOS) did not affect arterial stiffness, but lowered circulating levels of IL-6 and preserved endothelial function in patients with less damaged endothelium.133 Furthermore, some studies indicate decreased uremic toxin production in response to probiotics in experimental and clinical CKD, with ameliorated biomarkers of inflammation and oxidative stress.134 On the other hand, Borges et al.135 have found in a recent randomized, double-blind trial in haemodialysis patients a significant increase in IS plasma levels after three months of probiotic supplementation, which could be a consequence of increased permeability of the gut barrier. These findings highlight that probiotic therapy should be further explored but used with caution in CKD patients. Prebiotics, non-digestible carbohydrates that act stimulating the growth and activity of beneficial bacteria in the colon, have also been associated with reduction of uremic toxins and inflammatory markers in haemodialysis patients.136,137 On the other hand, in non-dialysis-dependent CKD patients, supplementation of FOS for three months did not lead to changes in uremic toxins levels.138 Likewise, symbiotics, which are defined as the combination of both prebiotics and probiotics, reduced levels of serum P-CS in CKD patients.134

Table 1: Potential factors acting as promoters or inhibitors of vascular calcification in the context of CKD and gut dysbiosis

| CKD                                               | Gut dysbiosis                             |
|---------------------------------------------------|-------------------------------------------|
| **VC promoters**                                  |                                           |
| TMAO                                              | TMAO                                      |
| Inflammatory cytokines                            | Inflammatory cytokines                    |

patients with moderate to severe CKD. This was followed by a more recent large, multinational, randomized clinical trial that unfortunately could not show a beneficial effect of AST-120 on the progression of CKD. An ongoing clinical trial aims to study the effects of oral absorbent and probiotics on vascular function of CKD patients. Overall, although some studies show promising effects of interventions aiming to promote gut health on intermediate endpoints, other studies show null results or even safety signals. This highlights the need for further studies to find efficient interventions, to identify relevant specific target (sub-)populations, and to demonstrate effects on clinically relevant (cardiovascular and bone) outcomes.

6 | CONCLUSIONS AND FUTURE PERSPECTIVES

In conclusion, CKD and gut dysbiosis share abnormalities in factors that promote or inhibit vascular calcification, as summarized in Table 1. Although a clear interplay exists between gut microbiota, bone health and vascular calcification (Figure 1), most studies to date focus on associations between two of these factors, but did not analyse all factors together. Therefore, there is still much to learn regarding the pathways that link gut microbiota to both bone and vascular health. To reach this aim, large, well-designed cohort studies addressing microbiome composition in relation to, preferably, both vascular calcification and bone disease in the setting of CKD are warranted.

Another major outstanding question, as also addressed in this review, is whether interventions targeting the microbiome improve cardiovascular and bone health in CKD. The difficulties regarding such studies rely among others on the lack of feasible and practical methods of evaluating changes in gut microbiome over time in a clinical trial. While it is important to address dietary and/or pro/prebiotic interventions modulating gut microbiota in trials in CKD patients aiming to assess their impact on gut metabolites (uremic toxins, TMAO, SCFA), it would be even more important to focus on markers of bone/vascular disease like fracture risk and CAC. Moreover, since current data seem to indicate heterogeneous efficacy of interventions targeting gut health regarding intermediate outcomes such as uremic toxins, it would be highly relevant to identify subgroups of patients that are potentially more susceptible to positive treatment response.
Although there may be a long road ahead, ultimately, correcting derangements in gut microbiota may be a promising approach to improve both bone and cardiovascular health in CKD patients.

CONFLICT OF INTEREST
The authors declare no conflicts of interest.

AUTHOR CONTRIBUTIONS
FGR conducted the research and wrote the manuscript. MSO discussed and enriched the manuscript. IPH, SJLB and MHB supervised and reviewed the manuscript.
