ABSTRACT

The 21-cm signal of neutral hydrogen is a sensitive probe of the Epoch of Reionization, Cosmic Dawn and the Dark Ages. Currently operating radio telescopes have ushered in a data-driven era of 21-cm cosmology, providing the first constraints on the astrophysical properties of sources that drive this signal. However, extracting astrophysical information from the data is highly non-trivial and requires the rapid generation of theoretical templates over a wide range of astrophysical parameters. To this end emulators are often employed, with previous efforts focused on predicting the power spectrum. In this work we introduce 21cmGEM – the first emulator of the global 21-cm signal from Cosmic Dawn and the Epoch of Reionization. The smoothness of the output signal is guaranteed by design. We train neural networks to predict the cosmological signal based on a seven-parameter astrophysical model, using a database of ~30,000 simulated signals. We test the performance with a set of ~2,000 simulated signals, showing that the relative error in the prediction has an r.m.s. of 0.0159. The algorithm is efficient, with a running time per parameter set of 0.16 sec. Finally, we use the database of models to check the robustness of relations between the features of the global signal and the astrophysical parameters that we previously reported. In particular, we confirm the prediction that the coordinates of the maxima of the global signal, if measured, can be used to estimate the Lyα intensity and the X-ray intensity at early cosmic times.

Key words: dark ages, reionization, first stars – cosmology: theory – galaxies: high redshift – software: development – intergalactic medium

1 INTRODUCTION

The exploration of the Universe out to times earlier than the point of complete reionization is rapidly advancing. One of the most informative probes of these epochs is the 21-cm line produced by hydrogen atoms in the neutral intergalactic medium (IGM) at redshifts z > 6. This line redshifts to frequencies below 200 MHz and can be detected by low-frequency radio telescopes. Global 21-cm experiments measure the spectrum of this line averaged over the sky. The first tentative detection of the Cosmic Dawn signal was recently made by the Low-Band implementation of the Experiment to Detect the Global EoR Signature (EDGES, Bowman et al. 2018). Other global 21-cm experiments, including the Large-Aperture Experiment to Detect the Dark Ages (LEDA, Bernardi et al. 2016; Price et al. 2018), the EDGES High-Band (Bowman & Rogers 2010; Monsalve et al. 2017, 2018, 2019), and the Shaped Antenna measurement of the background RAdio Spectrum (SARAS, Singh et al. 2017, 2018), provide upper limits on the signal from Cosmic Dawn and the Epoch of Reionization (EoR), ruling out some extreme astrophysical scenarios. A parallel effort is being made by interferometric radio arrays that are placing upper limits on the fluctuations of the 21-cm signal, including the Donald C. Backer Precision Array for Probing the Epoch of Reionization (PAPER, Kolopanis et al. 2019), the Low Frequency Array (LOFAR, Patil et al. 2017; Gehlot et al. 2019), the Giant Metrewave Radio Telescope (GMRT, Paciga et al. 2013), the Murchison Widefield Array (MWA, Beardsley et al. 2016; Barry et al. 2019), and the Owens Valley Radio

Observatory Long Wavelength Array (OVRO-LWA, Eastwood et al. 2019). Upcoming arrays, including the Hydrogen Epoch of Reionization Array (HERA, DeBoer et al. 2017), the Square Kilometer Array (SKA, Koopmans et al. 2015) and the New Extension in Nancay Upgrading LOFAR (NenuFAR, Zarka et al. 2012), will provide measurements of the power spectrum over a wide range of scales and redshifts.

The 21-cm signal is driven by both astrophysical and cosmological processes and is thus a unique probe of the early Universe. The amplitude of the 21-cm line observed against the radio background radiation, normally assumed to be the Cosmic Microwave Background (CMB; however, see Feng & Holder 2018; Ewall-Wice et al. 2018, 2019), depends on the abundance of neutral hydrogen atoms as well as on the contrast between the spin temperature, $T_S$ (the excitation temperature of the 21-cm transition), and the temperature of the background, $T_{\text{rad}}$. The former is driven to the kinetic temperature of the gas, $T_K$, by collisions as well as via absorption and re-emission of stellar Ly$\alpha$ photons (the Wouthuysen-Field (WF) coupling, Wouthuysen 1952; Field 1958). In the absence of collisions and/or Ly$\alpha$ radiation the spin temperature is driven to the temperature of the background. The gas is seen in absorption against the background if $T_S < T_{\text{rad}}$ (usually during the Dark Ages and Cosmic Dawn). Once the population of the first X-ray sources builds up and heats the IGM above the temperature of the background, the gas is seen in emission. In the course of reionization the abundance of neutral hydrogen atoms decreases and the IGM signal gradually vanishes. Overall, the signal measures properties of star formation, the abundance and luminosity of UV and X-ray sources, and, possibly, properties of dark matter if the latter has an effect on the thermal and ionization histories of the gas (e.g., Barkana 2018; Fialkov et al. 2018; D’Amico et al. 2018; Muñoz et al. 2015; Evoli et al. 2014; Tashiro et al. 2014).

Our currently limited knowledge about primordial star and black hole formation translates into large uncertainties in the predicted 21-cm signal. As a result, a wide space of astrophysical parameters should be explored when predicting the 21-cm signature. Because full-scale numerical simulations are prohibitively expensive, alternative techniques, such as fast algorithms, emulators, or machine learning methods, are often employed to walk through the allowed space of astrophysical signals (Greig & Mesinger 2015, 2017; Schnit & Pritchard 2018; Shimabukuro & Semelin 2017). The effort has so far focused on emulating the power spectrum of the 21-cm signal: Greig & Mesinger (2015) presented 21CMMC – a Monte-Carlo Markov Chain (MCMC) tool which returns three reionization parameters (the mean free path of ionizing photons, the minimum temperature of star forming halos and the ionizing efficiency of sources) given power spectrum measurements. Because X-ray heating might play an important role during the EoR (Mesinger et al. 2013; Fialkov et al. 2014), 21CMMC was recently extended to include three heating parameters: the bolometric luminosity of X-ray sources per unit star formation rate, as well as the low-energy cutoff and the slope of the X-ray spectral energy distribution (Greig & Mesinger 2017). Shimabukuro & Semelin (2017) took a different approach to find the best fit reionization parameters given power spectrum measurements: artificial Neural Networks (NNs) were trained on the data from 70 EoR simulations performed using the 21cmFAST code (Mesinger et al. 2011). The performance of the algorithm was tested on an additional set of 54 simulations. Schmit & Pritchard (2018) used NNs to emulate the power spectra generated by 21cmFAST and found a good agreement with 21CMMC. Finally, Kern et al. (2017) presented a more sophisticated emulator based on Gaussian processes, which could be applied to a broad range of problems. They demonstrate the performance on a six-parameter model for the 21-cm signal including reionization and heating parameters as well as five additional cosmological parameters. With the exception of Kern et al. (2017), all the above-mentioned tools are designed to reconstruct the parameters from a 21-cm power spectrum measurement. Similar tools specifically designed for the global 21-cm signal are lacking.

The recently reported results from EDGES Low-Band (Bowman et al. 2018) revealed an anomalously strong and narrow absorption feature at $\sim 78$ MHz which, if truly of cosmological origin, cannot be explained by the standard astrophysical model outlined above. One possible explanation is that dark matter scattered off baryons, draining energy from the gas and leading to its over-cooling (e.g., Barkana 2018; Fialkov et al. 2018; Muñoz et al. 2015; Muñoz & Loeb 2018). Another explanation invoked in the literature requires the existence of a strong radio background in addition to the CMB. Such an excess could be created by an anomalously bright population of high-redshift black holes at $z \sim 20$ (Bowman et al. 2018; Feng & Holder 2018; Ewall-Wice et al. 2018, 2019). As we await independent observational confirmation of the intriguing EDGES result, it is important to keep studying both the standard picture and exotic scenarios. In this paper we explore a wide range of standard astrophysical scenarios. We use a large dataset of models, which cover the widest astrophysical parameter space (see the next section), to develop a 21-cm global emulator ($\text{21cmGEM}$) for the first time. Given a set of seven astrophysical parameters, the emulator makes a prediction for the global 21-cm signal over a wide redshift range ($z = 5 - 50$) that includes both the EoR and Cosmic Dawn. Although our models do not capture the EDGES absorption feature, the algorithm developed here could be applied to a revised set of models with additional physics. $\text{21cmGEM}$, along with the global signals that were used to create the emulator, is publicly available at https://www.ast.cam.ac.uk/~afialkov/$. The tool has recently been employed to derive constraints on astrophysical parameters using the EDGES High-Band spectrum$^1$ (90190 MHz, Monsalve et al. 2019).

This paper is organized as follows. In Section 2 we detail our seven-parameter astrophysical model. In Section 3 we describe the simulation, the limits on the astrophysical parameter space, and the database of $\sim 30,000$ models. We also re-examine consistency relations between the astrophysical parameters and the features of the global signal first derived by Cohen et al. (2017). The design of the emulator is outlined in Section 4, and its performance assessed. Finally, we summarize our results in Section 5.

$^1$ Note that we previously referred to the emulator as $\text{GLOBAL21cm}$ (Monsalve et al. 2019).
2 THE HIGH-REDSHIFT UNIVERSE

The 21-cm signal from Cosmic Dawn and the EoR is driven by several astrophysical processes including star formation, heating and ionization. To produce the 21-cm signal we use our semi-numerical method (Visbal et al. 2012; Fialkov et al. 2014) which generates realizations of the universe in large cosmological volumes (384 comoving Mpc$^3$) and over a large redshift range ($z = 5 - 60$). The simulation follows the hierarchical growth of structure (including effects of the relative streaming velocity between dark matter and gas, Tseliakhovich & Hirata 2010), tracks star formation (averaged over a 3 Mpc scale) and follows the evolution of X-ray, Ly$\alpha$, Lyman-Werner (LW, 11.2-13.6 eV) and ionizing radiative backgrounds. The simulation takes into account the effect of the relative streaming velocity on star formation, as well as the effect of the LW radiation and of the photoheating feedback on star formation (see details below).

We parameterize the high-redshift astrophysics using seven key parameters: the star formation efficiency ($f_*$), the minimum circular velocity of star-forming halos ($V_c$), the X-ray radiation efficiency ($f_X$), power-law slope ($\alpha$) and low energy cutoff ($\nu_{\text{min}}$) of the X-ray Spectral Energy Distribution (SED), the mean free path of ionizing photons ($R_{\text{inj}}$) and the CMB optical depth ($\tau$).

2.1 Star formation

The simulation takes into account the effect of radiative and mechanical feedback processes on star formation. Star formation is possible in dark matter halos that are massive enough to enable efficient cooling of the in-falling gas (e.g., Tegmark et al. 1997). We use the threshold mass, or, equivalently (at a given redshift), the minimum circular velocity of star forming halos, as one of the free parameters. The lowest temperature coolant in the early Universe is molecular hydrogen, which allows stars to form in halos more massive than $M_{\text{min}}^{\text{cold}} \sim 10^7 M_\odot$, or with circular velocity larger than $V_c = 4.2$ km s$^{-1}$ (e.g., Tegmark et al. 1997; Barkana & Loeb 2001; Abel et al. 2002; Bromm et al. 2002; Yoshida et al. 2003). LW radiation produced by the first stars eventually halts star formation in molecular cooling halos (Haiman et al. 1997), shifting it to more massive atomic cooling halos of $M_{\text{min}}^{\text{atomic}} \sim 10^5 M_\odot$ ($V_c = 16.5$ km s$^{-1}$, Haiman et al. 2000; Machacek et al. 2001; Wise & Abel 2007; O’Shea & Norman 2008). The timing and duration of this transition is affected by uncertainties in the efficiency of the LW feedback (Visbal et al. 2014; Schauer et al. 2015). In addition, star formation in low-mass halos is modulated by the relative streaming velocity between dark matter and baryons (e.g., Tseliakhovich & Hirata 2010; Dalal, Pen, & Seljak 2010; Visbal et al. 2012; Fialkov et al. 2012). On the other hand, the minimum cooling mass can rise above the atomic cooling threshold via feedback mechanisms such as supernova explosions (e.g., Wyithe & Loeb 2013). At lower redshifts, when reionization becomes significant and the gas in the IGM is heated above $10^6$ K, photoheating feedback becomes important. This feedback mechanism prevents further accretion of gas onto halos below $10^8 - 10^9 M_\odot$ ($V_c$ up to $\sim 75$ km s$^{-1}$, e.g., Rees 1986; Weinberg et al. 1997; Navarro & Steinmetz 2000; Sobacchi & Mesinger 2013; Cohen et al. 2016). For the study presented here we vary the starting value of $V_c$ (before additional feedbacks are imposed) in the range: $2.1 - 6.5$ km s$^{-1}$.

The fraction of gas in dark matter halos that is converted into stars, referred to as the star formation efficiency, is another free parameter in the simulation. In general, this quantity depends on the halo mass. The observed star formation efficiency peaks at a value of a few percent in halos of $\sim 2.8 \times 10^{11} M_\odot$ (e.g., Mirocha et al. 2017): as it is regulated by feedback mechanisms, the process is less efficient in both higher-mass and lower-mass halos. Star formation in the low-mass halos characteristic of the high redshift Universe is virtually unconstrained by observations, while numerical simulations yield a large scatter, finding an efficiency of a few percent or much lower (Jeon et al. 2014; Wise et al. 2014; O’Shea et al. 2014). To parameterize the process of star formation in our simulations we assume constant star formation efficiency in halos heavier than the atomic cooling mass (and this value we designate $f_*$), while in lower mass halos a logarithmic cutoff in the efficiency is employed (see Cohen et al. 2017, for more details). We vary $f_*$ between 0.0001 and 0.5.

2.2 Heating

The least constrained component of the modeling is the set of properties of the first X-ray sources that heat up the cosmic gas. The most plausible sources that dominate the X-ray radiative background at high redshifts are X-ray binaries (XRBs, Mirabel et al. 2011; Fragos et al. 2013); however, other candidates have also been discussed in the literature, including hot gas in galaxies, mini-quasars (Madau et al. 2004), X-rays produced via inverse Compton scattering of the CMB photons off electrons accelerated by supernovae (Oh 2001), or more exotic scenarios such as dark matter annihilation (e.g., Cirelli et al. 2009; Liu et al. 2019).

The spectral energy distribution (SED) of the early X-ray sources is a key astrophysical parameter (Fialkov et al. 2014) and might strongly affects the 21-cm signal from both the EoR and Cosmic Dawn. The effect of hard X-ray sources with energy around 2 keV on the thermal and ionization histories (and, thus, on the resulting 21-cm signal) is significantly different from that of soft sources with energies of $\sim 0.5$ keV: soft sources generate strong fluctuations on relatively small scales (up to a few tens of comoving Mpc) in the gas temperature and, subsequently, in the 21-cm intensity; on the other hand, hard sources produce a more homogeneous and less efficient heating, generating mild fluctuations on larger scales (> 100 comoving Mpc). XRBs, as well as miniquasars, have a hard spectral energy distribution (see the discussion in Fialkov et al. 2016) that peaks at a few keV, while other sources can have softer SEDs. Absorption of soft X-rays with energy lower than $\nu_{\text{min}}$ (typically of $\sim 0.1 - 0.5$ keV) by dust in the host galaxy could contribute to effective hardening of X-ray SEDs (Fragos et al. 2013). We parameterize the X-ray SED by a power-law of the slope $\alpha$ (i.e., $d \log(E_X)/d \log(\nu) = -\alpha$) and a low-frequency cutoff $\nu_{\text{min}}$. Since there is significant degeneracy between these two parameters, we vary $\alpha$ only slightly (in the range: $\alpha = 1 - 1.5$), and $\nu_{\text{min}}$ in the wide range of $0.1 - 3$ keV.

In addition to the shape of the SED, the total X-ray luminosity of sources is the other important parameter. Here
we adopt the standard expression for the luminosity per star formation rate \( L_X - \text{SFR} \) relation, see Piankov et al. 2014; Cohen et al. 2017, for more details) inferred from low-redshift observations of nearby starburst galaxies and XRBs (Grimm et al. 2003; Gilfanov et al. 2004; Mineo et al. 2012):

\[
\frac{L_X}{\text{SFR}} = 3 \times 10^{40} f_X \text{ erg s}^{-1} \text{ M}_\odot^{-1} \text{ yr}.
\]

In the above expression \( L_X \) is the bolometric luminosity, and \( f_X \) is the (constant) X-ray efficiency of sources, which we use as the third X-ray parameter. The standard normalization for XRBs (with \( f_X = 1 \)) takes into account an order-of-magnitude increase in the \( L_X - \text{SFR} \) relation in the low-metallicity environments expected at high redshifts (Fragos et al. 2013). The high-redshift \( f_X \) is poorly constrained: A model-dependent upper limit of \( f_X \sim 10 - 1000 \) can be derived using the measurement of the unresolved cosmic X-ray background (Piankov et al. 2016); a lower (also model-dependent) limit of \( f_X \sim 0.001 \) is hinted at by 21-cm experiments (Singh et al. 2017; Cohen et al. 2019). Here we vary \( f_X \) between 0 and 10.

2.3 Reionization

We parameterize the process of reionization with two parameters: The first parameter is the mean free path of ionizing photons, \( R_{\text{adfp},\nu} \), which we vary between 10 and 50 comoving Mpc (Alvarez et al. 2012; Greig & Mesinger 2015). This parameter approximately quantifies the effect of dense small-scale absorption systems in that it is the mean free path of ionizing photons in a large-scale ionized bubble. In practice it is set as an upper limit on the distance to sources that can participate in the reionization of a given cell. The second EoR parameter is the ionizing efficiency of sources, defined as

\[
\zeta = f_x f_{\text{esc}} N_{\text{ion}} \frac{1}{1 + \tilde{n}_{\text{esc}}},
\]

where \( f_{\text{esc}} \) is the fraction of ionizing photons that escape into the IGM, \( \tilde{n}_{\text{esc}} \) is the mean number of recombinations per ionized hydrogen atom, and \( N_{\text{ion}} \) is the number of ionizing photons produced per stellar baryon. Given a star-formation history and assuming a mass-independent ionizing efficiency, there is a one-to-one relation between \( \zeta \) and the CMB optical depth. Because \( \tau \) (rather than \( \zeta \)) is directly probed by the CMB experiments (specifically by the Planck satellite, Planck Collaboration 2016), we choose to work with \( \tau \) as the free parameter. Taking the Planck measurement as a reference, we vary \( \tau \) between 0.055 and 0.1; we find it difficult to produce \( \tau \) below 0.055 and still be consistent with other observational constraints (see below).

The non-linear mapping between \( \tau \) and \( \zeta \), which is a function of the other input astrophysical parameters, is carried out using a NN which was trained on a set of 27,455 cases and tested with 2,186 cases. As is detailed in Section 4, several NNs are employed throughout this work. We always use one hidden layer of 40 neurons, and the Levenberg-Marquardt algorithm to minimize the mean-square error between the true value provided by the training dataset and the value predicted by the network. We evaluate the performance of the NN by quantifying its accuracy in predicting \( \zeta \). The histogram of the relative errors is shown in Fig. 1. The mean relative error is 0.77% and 76% of the cases have a relative error smaller than 1%.

2.4 Observational Constraints

The parameter space outlined above is constrained by the available observations of the EoR. In addition to the limits on \( \tau \) from the CMB experiments, we incorporate two other types of constraints when developing the global signal emulator:

- (i) Stellar models indicate that for the extreme case of massive population III stars, \( N_{\text{ion}} = 40,000 \) (Bromm 2001); therefore, we set an upper limit of \( \zeta_{\text{max}} = 40,000f_x \) based on Eq. 2. Hence, our first requirement for a parameter set to be valid is that \( \zeta < \zeta_{\text{max}} \).

- (ii) Absorption seen in the spectra of high-redshift quasars measures the neutral fraction of the Universe (e.g., Bañados et al. 2018). A 2\( \sigma \) upper limit of \( x_{\text{HI, max}}(z = 5.9) = 16\% \) on the neutral fraction at \( z = 5.9 \) (\( \nu = 205.85 \) MHz) was derived from quasar absorption troughs (McGreer et al. 2015). Our second requirement is, thus, \( x_{\text{HI}}(z = 5.9) < 16\% \). In this paper we do not take into account the latest constraints from the Ly-\( \alpha \) emitting galaxies (Mason et al. 2019) and high redshift quasars (e.g., Bañados et al. 2018) as they became available when our paper was close to being completed (however, see Monsalve et al. 2019).

Because the reionization history depends on several astrophysical parameters simultaneously, the above-mentioned constraints condition the entire parameter space. Figure 2 illustrates the mapping between the EoR constraints and the allowed regions in the \( f_x - V_c \) plane for the specific choice of the EoR parameters, \( \tau = 0.055 \) and \( R_{\text{adfp},\nu} = 50 \) Mpc. The allowed region is white, the excluded region with \( \zeta > \zeta_{\text{max}} \) is shown in blue, while the region with \( x_{\text{HI}}(z = 5.9) > 16\% \) is red. The area where the two exclusion criteria overlap is painted in black.

The shape of the excluded and allowed regions is easy
to understand. Consider first the requirement $\zeta < \zeta_{\text{max}}$. For given values of $\tau$ and $R_{\text{mfp}}$ (as well as the fixed heating parameters of $f_X = 1$, $\alpha = 1.5$ and $\nu_{\text{min}} = 0.2$ keV), models with a low star formation efficiency require high values of $\zeta$ that exceed the upper limit. Therefore, cases with low $f_s$ are excluded. Now, the lower the value of $V_c$, the more star forming halos there are, making it easier to reionize (and match the required value of $\tau$) without needing to exceed $\zeta_{\text{max}}$. Therefore, the maximum excluded $f_s$ is a monotonically growing function of $V_c$. This function grows rapidly at the highest $V_c$ due to the exponential dependence of the halo abundance on $V_c$, while it changes slowly at $V_c < 16.5$ km s$^{-1}$ because in this mass range the number of stars at a given $f_s$ is regulated by the LW feedback by the time of the bulk of cosmic reionization.

Consider the second requirement, $x_{\text{HI}}(z = 5.9) < 16\%$. Since $\tau$ has fixed the average timing of reionization, the neutral fraction constraint rules out cases with low $V_c$, since these are characterized by a more gradual evolution of reionization and, thus, a higher remaining neutral fraction at $z = 5.9$, regardless of the values of the other parameters. Therefore, this requirement rules out the left portion of the $f_s - V_c$ plane (for a fixed $R_{\text{mfp}}$).

The exclusion contours for several choices of $\tau$ and $R_{\text{mfp}}$ at the fixed values of the heating parameters are shown in the left panel of Figure 3, with the previously examined (reference) case of $\tau = 0.055$ and $R_{\text{mfp}} = 50$ Mpc shown in solid blue. A lower $R_{\text{mfp}}$ implies a more gradual end to reionization (thus raising the residual $x_{\text{HI}}$ at $z = 5.9$) since sources then cannot contribute ionizing photons beyond this shorter distance. A higher $\tau$ moves the bulk of reionization towards higher redshifts, making it more compatible with the observational constraint at the fixed redshift of 5.9. With a lower $R_{\text{mfp}}$ of 10 Mpc (solid red), the excluded area is larger with a lowest allowed value of $V_c = 52$ km s$^{-1}$ ($\sim 28 \times M_{\text{min}}^{\text{atomic}}$), compared to 29 km s$^{-1}$ ($\sim 5 \times M_{\text{min}}^{\text{atomic}}$) for the reference case. Increasing $\tau$ (the dashed lines correspond to $\tau = 0.064$) allows a wider range of $V_c$. In that case, if $R_{\text{mfp}} = 10$ Mpc (dashed red) then only $V_c < 6.3$ km s$^{-1}$ is excluded, and even that is only if $f_s \lesssim 0.25$. At the highest star formation efficiencies, partial ionization by X-rays becomes significant, speeding up the process of reionization.

After searching over the full range of $R_{\text{mfp}}$ and the heating parameters, we show the absolutely excluded regions for various values of $\tau$ in the right panel of Fig. 3; i.e., these are regions that are always excluded, there is no averaging here. We found a lower limit for the optical depth of $\tau = 0.046$. For the best-fit Planck value of $\tau = 0.055$ we found lower limits on the circular velocity of $V_c \sim 26$ km s$^{-1}$ ($\sim 4 \times M_{\text{min}}^{\text{atomic}}$) and on the star formation efficiency of $f_s \sim 0.0004$. However, for $\tau = 0.064$ (1σ away from the best-fit Planck measurement) no values of $V_c$ are excluded and the absolute minimum on the star formation efficiency is $f_s \sim 0.0002$.

Based on the observational constraints we train a NN to verify if the input set of astrophysical parameters has a valid reionization history. Specifically, the NN predicts at which frequency, denoted by $\nu_{16\%}$, the neutral fraction reaches 16% for the given set of astrophysical parameters, $\nu_{16\%} = \nu (x_{\text{HI}} = 0.16)$. The reionization history is valid if this frequency is lower than 205.85 MHz (i.e., the redshift is higher than 5.9). Because for many cases $x_{\text{HI}}(z = 5.9)$ is zero, $\nu_{16\%}$ can be more easily inferred with high accuracy than the neutral fraction at $z = 5.9$. The performance of the NN in predicting $\nu_{16\%}$ is evaluated in Figure 4 where we show the histogram of relative errors. We find that the mean relative error is 0.47% and 92% of cases have a relative error smaller than 1%.

Thus, in order to incorporate the observational constraints, the only information that we pass to the global signal emulator (as described in detail in Section 4) is whether or not an input parameter set renders a valid EoR history, i.e., given the generated values of $\zeta$ and $\nu_{16\%}$, whether $\zeta < \zeta_{\text{max}}$ and $\nu_{16\%} < 205.85$ MHz. The success/failure rates of the classification process is summarized in the form of confusion matrices shown in Figure 5. Out of 2186 tested cases, 348 are excluded based on their values of $\zeta$ and 117 are excluded based on the values of $\nu_{16\%}$ (22 overlap, i.e., are inconsistent with either constraint). The classification is done correctly in 100% of cases for $\zeta$, and in 99.9% of cases for $\nu_{16\%}$.

### 2.5 Dataset

Using the modeling outlined above we created a dataset of 29,641 global 21-cm signals that cover a very wide range of possible values of the seven astrophysical parameters, $V_c = 4.2 - 100$ km s$^{-1}$, $f_s = 0.0001 - 0.50$, $\alpha = 1 - 1.5$, $\nu_{\text{min}} = 0.1 - 3$ keV, $f_X = 0 - 1000$, $\nu = 0.04 - 0.2$, $R_{\text{mfp}} = 10 - 50$ Mpc, and verifying whether or not the ionization history complies with the EoR constraints (subsection 2.4). The sampling of the parameter space was done randomly with uniform priors on $\log_{10} (V_c)$, $\log_{10} (f_s)$, $\log_{10} (f_X)$, $R_{\text{mfp}}$ and $\zeta$. The SED was randomly chosen with $\alpha = 1, 1.3$ or 1.5, and $\nu_{\text{min}} = 0.1, 0.2, 1$ or 3 keV. The 21-cm spectra are created over the redshift range $z = 5 - 50$ and are sampled at $\Delta z = 0.1$. The set of models was (randomly) split into the training and testing sets. The parameters of the testing set are restricted to $V_c = 4.2 - 76.5$ km s$^{-1}$, $f_s = 0.0001 - 0.50$, $\alpha = 1 - 1.5$, $\nu_{\text{min}} = 0.1 - 3$ keV, $f_X = 0 - 10$, $\nu = 0.055 - 0.1$, $R_{\text{mfp}} = 10 - 50$ Mpc over which ranges the performance of 21cmGEM was opti-
Figure 3. Left panel: The total exclusion contours (the excluded regions are under and to the left of the curves) for $\tau = 0.055$ (solid lines), $\tau = 0.05$ (dashed), $R_{\text{mfp}} = 10$ Mpc (red) and $R_{\text{mfp}} = 50$ Mpc (blue). The same X-ray parameters as in Figure 2 were assumed. Right panel: The total exclusion contours are shown for $\tau = 0.049$ (red), 0.052 (orange), 0.055 (green), 0.060 (cyan) and 0.064 (blue); these are the regions that are excluded for all values of $R_{\text{mfp}}$ and X-ray parameters that we consider (i.e., these are not averaged over those parameter regions). The highest $\tau$ which is completely excluded within our parameter space is $\tau = 0.046$.

3 CONSISTENCY RELATIONS

Cohen et al. (2017) derived universal relations between astrophysical quantities (such as the heating rate, $\epsilon_X$, and the intensity of the Ly$\alpha$ background, $J_{\alpha}$), and the three key points of the global signal, including the high-$z$ maximum at the redshift labeled $z_{\text{max}}^\text{hi}$ (at matching frequency $\nu_{\text{max}}^\text{hi}$) and the brightness temperature $T_{\text{max}}^\text{hi}$; the absorption trough located at $z_{\text{min}}$ (or $\nu_{\text{min}}$) and reaching $T_{\text{min}}$; and the low-$z$ maximum at $z_{\text{max}}^\text{lo}$ (or $\nu_{\text{max}}^\text{lo}$) with $T_{\text{max}}^\text{lo}$. That work was based on a dataset of 200 signals generated using a 5-parameter model ($V_c, f_*, \tau, f_X$ and either a hard or soft X-ray SED) with the parameters sampled on a grid (see Cohen et al. 2017, for a detailed description of the sampling). Here we verify the validity of the above-mentioned relations in the context of our extended 7-parameter model and using a subset of 1948 randomly drawn combinations of the parameters.

At the onset of Cosmic Dawn the 21-cm signal is driven by atomic physics and the early process of Ly$\alpha$ coupling due to star formation, which results in a close relation between $z_{\text{max}}^\text{hi}$ and $T_{\text{max}}^\text{hi}$ as shown in Fig. 6. There is low scatter relative to a relation that can be fitted with a quadratic function of the form

$$r_{\text{max}}^\text{hi} = a \left(1 + z_{\text{max}}^\text{hi}\right)^2 + b \left(1 + z_{\text{max}}^\text{hi}\right) + c .$$

Using the extended dataset we find a similar relation to the one reported by Cohen et al. (2017) (Eq. 8 and Fig. 2 in that paper), with the best-fit parameters changed by 10-20%. The new best-fit values are $[a, b, c] = [-0.029, 1.053, -0.667]$.

The value of $z_{\text{max}}^\text{hi}$ (and, hence, the value of the brightness temperature at this redshift) directly depends on the intensity of the Ly$\alpha$ background that drives the WF coupling. Therefore, it is natural to expect that the intensity of the Ly$\alpha$ background can be inferred from the high-redshift maximum of the signal. Following Cohen et al. (2017) [see their Eqs. 9 and 10 and Fig. 3], we examine the relationship between $z_{\text{max}}^\text{hi}$ and the mean Ly$\alpha$ intensity measured at this redshift, as well as its derivative with respect to the scale factor $a = 1/(1 + z)$, and show the new results in Fig. 7. The best fits to the new data are:

$$\log(J_{\alpha}) = a_1 \log^2 \left(1 + z_{\text{max}}^\text{hi}\right) + b_1 \log \left(1 + z_{\text{max}}^\text{hi}\right) + c_1 ,$$

and

$$\log \left(\frac{J_{\alpha}}{dz}\right) = a_2 \log^2 \left(1 + z_{\text{max}}^\text{hi}\right) + b_2 \log \left(1 + z_{\text{max}}^\text{hi}\right) + c_2 ,$$

where $[a_1, b_1, c_1] = [-10.64, 37.15, -54.31]$ and $[a_2, b_2, c_2] = [-7.851, 30.34, -47.73]$. On average we find a good agreement between the new study and the results of Cohen et al. (2017). However, the scatter in $J_{\alpha}$ is now substantially larger due to the contribution of X-rays to the Ly$\alpha$ background via X-ray excitation of neutral hydrogen.

The complexity of the Universe increases as the population of the first heating sources forms. The location and the
Figure 5. Left panel: The confusion matrix of the exclusion process $\zeta > \zeta_{\text{max}}$. Right panel: The confusion matrix of the exclusion criterion $\nu_{216} > 205.85$ MHz. The structure of each confusion matrix is as follows: Each matrix has 9 fields with the green squares showing the number of excluded and allowed cases which were correctly classified, red squares showing the number of miss-classified cases, grey showing the percentage of the correct predictions for each row/column, and blue showing the total accuracy defined as the ratio of the total number of correctly identified cases (both excluded and allowed) to the total number of considered cases.

Figure 6. Brightness temperature as a function of the observed frequency at the high-redshift maximum point. The colors indicate the value of $V_c$ as indicated on the colorbar: dark blue corresponds to the lowest value of $V_c$ (4.2 km s$^{-1}$), and dark red corresponds to its highest value (76.5 km s$^{-1}$). Also shown is a fitting function (Eq. 3, solid) along with our older fit from Eq. 8 of Cohen et al. (2017) (dashed) for comparison. Black x’s show models that were excluded by our observational constraints.

The predicted class of the 21-cm signal is shown in the left panel of Fig. 8 color-coded as a function of $\nu_{216}$, where $\nu_{216}$ is close to the kinetic temperature of the gas (and the absorption trough is shallower). On the other hand, the role of the X-ray sources is to heat up the gas: the weaker the heating is, the more time the Universe has to cool down as a result of the adiabatic expansion. Therefore, we get a lower limit given by the strongest possible absorption in the case of a fully coupled, adiabatically cooled gas:

$$T_{\text{min}} \geq 26.8 \left(\frac{1 + z_{\text{min}}}{10}\right)^{1/2} \left(1 - \frac{1 + z_{\text{dec}}}{1 + z_{\text{min}}}\right) \text{mK}, \quad (6)$$

where $z_{\text{dec}} = 137$ (Cohen et al. 2017). The depth of the absorption trough as a function of $\nu_{216}$ is shown in the left panel of Fig. 8 color-coded as a function of $f_X$.

Cohen et al. (2017) suggested that the ratio between the Ly-\(\alpha\) intensity and the X-ray heating rate can be inferred from the value of the brightness temperature at the minimum point. The right panel of Figure 8 shows that this does not entirely persist. The larger variation in the properties of X-ray sources employed here compared to what was implemented by Cohen et al. (2017), results in a large scatter in the $\nu_{216}/\epsilon_X$ relation. In particular, models with very low $f_X$ (values that are unusually low compared with low-redshift galaxies, but are still possible) break this relation. As shown in the figure, this is the case only for models for which the measured value of $z_{\text{min}}$ would be low.

Finally, we examine the emission peak of the 21-cm signal during the EoR. As was pointed out by Fialkov et al. (2014), for a large part of the astrophysical parameter space X-ray heating plays a major role in the 21-cm signal during the EoR. Specifically, in cases of extremely inefficient heating there is no transition of the 21-cm signal into emission feature depend not only on the EoR parameters but also on the heating rate (as well as on the parameters of star formation). Because of the complex dependence, one would expect to find a large scatter in the values of $(z_{\text{min}}/T_{\text{max}})$.

However, as can be seen from the left panel of Figure 9 (see also Eq. 15 and Fig. 7 of Cohen et al. 2017), the scatter is relatively low because the EoR history is significantly constrained by current observations (Section 2.4). The location and amplitude of the emission peak for the present dataset are in good agreement with our previous results.
relation can be fitted with:

\[
T_{\text{lo}}^{\text{max}} = \begin{cases} 
  a \frac{1}{1+z_{\text{lo}}^{\text{max}}} + b & \text{if } 1+z_{\text{lo}}^{\text{max}} > \frac{a}{b} \\
  0 & \text{otherwise}
\end{cases}
\]  

(7)

where \([a, b] = [-500.1, 59.05]\).

The right panel of Fig. 9 shows the relation between the amplitude of the emission feature and the heating rate at \(z_{\text{lo}}^{\text{max}}\), which can be fitted with

\[
\log (\epsilon_X) = aT_{\text{lo}}^{\text{max}} + b,
\]

(8)

with \([a, b] = [0.07026, -17.95]\). While there is significant scatter, this dependence can be used to constrain the properties of X-ray sources directly from the measurement of the global 21-cm signal.

4 21CMGEM: THE GLOBAL SIGNAL EMULATOR

The main product of this work is the global signal emulator which, given a set of 7 input astrophysical parameters, outputs a realization of the global 21-cm signal sampled at \(\Delta z = 0.1\) over the redshift range \(z = 5 - 50\). In addition to the 21-cm spectrum, 21CMGEM outputs values of the neutral fraction at \(z = 5.9, z = 7.08\) and \(z = 7.54\) along with frequencies at which the neutral fraction is 0.16% and 11%. This auxiliary information could be used to apply external constraints to the models (see Monsalve et al. 2019).

Designed to detect features in the global 21-cm signal, the total-power experiments are very sensitive to steps and wiggles in the data. To avoid spurious apparent detections, the smoothness of the mock 21-cm signal over the entire observed frequency band is one of the major requirements. Predicting the signal in each frequency bin separately (as is done with the power spectrum emulators) is not sufficient.
as it leads to discontinuities in the spectrum. Instead, our approach here is to decompose the signals onto a new basis of smooth functions that span the entire simulated dataset. Principal Component Analysis (PCA) is employed to find the basis of such functions. Dividing the entire database into training and testing sets, we train neural networks to predict the PCA coefficients, along with the key points of the global signal, for any input set of astrophysical parameters. This information is then used to generate the output 21-cm signal. The main steps of the emulation process, as well as details of the training and optimization of the algorithm, are described in the rest of this section.

4.1 Design

4.1.1 Classification

As our parameter study shows, all the analyzed global signals have a universal shape featuring a high redshift maximum and an absorption trough (Note: for a reminder of the overall shape of the global 21-cm signal, see the examples shown in Fig. 15). The only non-universal feature is the emission signal during the EoR which is either present (we refer to this type of signal as positive) or not (negative signals) depending on the astrophysics. Because of this fundamental difference in the shape of the signals, our algorithm is two-fold and treats the two types of signals separately. The classification into positive and negative cases is an essential part of the training and the prediction processes. If the signal is positive, it has four key points: the high-redshift maximum, absorption trough, low-redshift maximum and the redshift of complete reionization ($\nu_{\text{hi}}^{\text{max}}, \nu_{\text{min}}, \nu_{\text{max}}^{\text{low}}$, and $\nu_{\text{reion}}$, respectively). A negative signal has only 3 key points ($\nu_{\text{hi}}^{\text{max}}, \nu_{\text{min}}$, and $\nu_{\text{reion}}$, respectively). The key points divide each positive (negative) case into 3 (2) segments. As we detail in the next subsection, each segment is analyzed separately using the PCA.

The bagged trees algorithm was used to determine whether a case is negative or positive. This algorithm fits many decision trees, each time using a different subset of the training set, and the decision is made by voting. After optimization we chose to use bagged trees with 30 tree learners and tree size chosen using 5-fold cross-validation. The classification was tested on 1014 negative and 580 positive cases. We first tested the accuracy of the classification process against each of the test cases and visually compared the results to assess the performance. Knowing the location of the emission feature (low-z maximum point) compared to the timing of the other key points helps to improve the quality of the classification. Before this information was added, 5.5% of negative cases were mis-classified as positive. After the optimization, the algorithm returned the correct answer in 99.9% of cases. The final confusion matrix is shown in Figure 10. Note that for this test we only used cases with $T_{\text{max}} > 0.2$ mK. This is because cases with a lower (but still positive) emission peak are really neither positive nor negative, and mis-classification in this case does not lead to an inaccurate prediction of the 21-cm signal itself.

4.1.2 PCA

The core of our emulator is PCA which, given a database, finds an orthogonal basis that spans the data. Eigenfunctions (or eigenvectors) of this basis are smooth functions found using the covariance matrix of the data; while eigenvalues are a measure of the variance of the data along each particular eigenvector. The basis is constructed so that the first principal component (the eigenvector with the largest eigenvalue) has the largest possible variance, the component with the second greatest variance is the second principal component, and so on. Using the basis of smooth functions to represent the 21-cm signal guarantees the smoothness of the outcome.

The astrophysical key points divide each positive/negative signal into 3/2 distinct frequency segments. For a positive signal the segments are $s_1 \in [\nu_{\text{hi}}^{\text{max}}, \nu_{\text{min}}]$, $s_2 \in [\nu_{\text{min}}, \nu_{\text{max}}^{\text{low}}]$, and $s_3 \in [\nu_{\text{max}}^{\text{low}}, \nu_{\text{reion}}]$; while for a negative signal the segments are $s_1 \in [\nu_{\text{hi}}^{\text{max}}, \nu_{\text{min}}]$ and $s_2 \in [\nu_{\text{min}}, \nu_{\text{reion}}]$. 

\[ \]
We find it best to split the data into these segments and analyze them separately. Note that, because the first segment, $s_1$, is defined identically for both positive and negative cases, over $s_1$ all signals are analyzed together; while over other segments the positive and negative cases are treated separately. In order to uniformly normalize the signals within each segment of the data, we perform a coordinate transformation into a new coordinate system $x_s, y_s$ in which each signal varies in the range $x_s \in [0, 1]$ and $y_s \in [-1, 1]$. For instance, on $s_1$ the following coordinate transformation from the $\nu - T_{21}$ plane to the $x_s - y_s$ plane is performed:

$$
x_s = \frac{\nu - \nu_{\text{hi}}}{\nu_{\text{max}} - \nu_{\text{min}}}, \quad y_s = \frac{T - T_{\text{hi}}}{T_{\text{max}} - T_{\text{min}}}. \quad (9)
$$

In other words, for both the negative and positive signals $s_1$ is chosen so that $(\nu_{\text{hi}}, T_{\text{max}})$ is mapped to $(x_s, y_s) = (0, 0)$, and the minimum point $(\nu_{\text{min}}, T_{\text{min}})$ is mapped to $(x_s, y_s) = (1, -1)$. Each re-normalized segment is separately analyzed using PCA.

In principle, for a perfect reconstruction of the signal via PCA decomposition the number of coefficients should be the same as the size of the database (i.e., $\sim 30,000$ in our case). However, for our dataset the first four eigenvalues strongly dominate, allowing us to truncate the basis and use only the first four eigenfunctions to represent the signal in each segment. Fig. 11 is an illustration of the PCA decomposition for a signal over $s_1$. We show a re-normalized signal (blue) and the first four eigenfunctions of the basis (shades of brown). The red curve shows the sum of the first four PCA components (each with its corresponding coefficient), reproducing the true signal nearly perfectly. We quantify the accuracy of the reconstruction process along each segment by calculating the r.m.s. of the error defined as

$$
\text{RMS} = \sqrt{\text{mean} \left[ (y_{s, \text{sim}}(x_s) - y_{s, \text{pred}}(x_s))^2 \right]} . \quad (10)
$$

The mean r.m.s. error across all the reconstruction cases is 0.0020 on $s_1$, 0.0058 and 0.0075 on $s_2$ and $s_3$, respectively, and 0.0045 for $s_4$.

### 4.1.3 Training of the NNs

Having created the PCA decomposition for each set of astrophysical parameters from the training dataset of 27,455 cases, we tabulated the values of the PCA coefficients along with the key points (both the frequency and the corresponding brightness temperature of each key point). Using this library, NNs were trained to retrieve the PCA coefficients along with the values of the key points given an input set of the astrophysical parameters.

We found that the accuracy of the prediction is improved if we add to the modeling combinations of the astrophysical parameters that we expect to map more directly to the 21-cm signal. We made use of the fact that we know the simulated cosmology. Assuming the standard collision-less cold dark matter scenario and hierarchical structure formation, we can infer the mean collapse fraction at every redshift ($f_{\text{coll}}(z)$), the fraction of mass that is contained in halos of mass above the minimum cooling threshold, Barkana & Loeb (2004). We appended five more parameters to the original set of the seven astrophysical parameters, including $f_{\text{X}\text{R} > 1\, \text{keV}}(20)$ which is proportional to the intensity of the Ly$\alpha$ radiation before the Ly$\alpha$ coupling; $f_{\text{XR} \text{X}\text{R} > 2\, \text{keV}}(15)$ which scales as the intensity of X-ray radiation before the heating saturation; and $\zeta_{\text{coll}}(10)$ which is a measure of the ionizing radiation at the onset of reionization. In addition, we added the fraction of X-ray energy above 1 keV and the fraction of X-ray energy above 2 keV ($f_{\text{XR} \text{X}\text{R} > 1\, \text{keV}}(20)$ and $f_{\text{XR} \text{X}\text{R} > 2\, \text{keV}}(15)$, respectively) to characterize the X-ray SED. Lastly, we applied physical cuts on the predicted signal to assist the NNs. In particular, an upper limit of $T_{\text{max}}^{\text{hi}} = 0$ was imposed because $T_{\text{max}}^{\text{hi}}$...
is expected to always be negative in the range of scenarios considered here. We also set a lower limit on the signal at the minimum point, \( T_{\text{min}} \), in accordance with Eq. 6.

In total, predicting a positive/negative signal requires generating 19/13 parameters: four PCA coefficients for each of the three/two segments plus four/three key points each having two coordinates (frequency and brightness temperature), minus one degree of freedom because the value of the brightness temperature at \( \nu_{\text{el}} \) is by definition zero. As part of the optimization process we had to choose between using one network which would predict all the 19/13 output parameters, 19/13 networks each of which would return a single parameter, or a few NNs predicting groups of the parameters. We found that predicting several parameters with a single network sometimes decreases the error in the predicted signal. However, it also can result in outliers, i.e., a few cases with very large error. To minimize the frequency of outliers while preserving the overall accuracy, we decided to group correlated parameters within the same network. For instance, the four PCA components of a given segment are correlated and were computed with a single NN. The outcome of this prediction is demonstrated in Fig. 11 (dashed black line). Using Eq. 10 we assessed the performance of the prediction process and found an r.m.s. error of 0.023 on \( T_{\text{min}} \), 0.055 and 0.136 on \( s_2^s \) and \( s_2^\nu \) respectively, and 0.031 on \( s_2^\nu \).

Separate NNs were trained to predict the coordinates of the critical points in the \( \nu - T_{21} \) space. The accuracy of the reconstruction of these coordinates is summarized in Table 1. We found that the algorithm is well tuned to predict the signal from Cosmic Dawn, with 100% of cases having better than 5% accuracy in the amplitude and the location of the high-redshift maximum, and more than 98% of cases having better than 5% accuracy in the prediction of the depth and location of the absorption trough. The low-redshift maximum point is the hardest to predict since it is affected by all the astrophysical parameters and also the amplitude of the signal at this point is quite small. In addition, because this feature does not exist for negative cases, the training dataset which could be used for \( (\nu_{\text{lo}}^\nu, T_{\text{max}}^\nu) \) was smaller. The maximal absolute error obtained when predicting \( T_{\text{max}}^\nu \) was 2.3 mK, with 59.87% of cases returning relative errors smaller than 5%. In 98.57% of cases \( \nu_{\text{lo}}^\nu \) was found to be lower than a 5% error. Finally, the success rate for the prediction of the timing of reionization was close to 100%.

As an illustration, in Fig. 12 we show the accuracy of the algorithm in reconstructing the amplitude of the absorption feature for 1,743 cases (all our test cases that were not excluded by the observational constraints in section 2.4). The line \( Y = X \) corresponds to a perfect prediction. The scatter shows the error in this prediction, which is also quantified in the histogram (right panel). We find that 98.28% of cases have a relative error of less than 5%, while 78.88% of cases have an error less than 2% (as indicated in Table 1).

### 4.2 Prediction Pipeline

Using the trained NNs the global 21-cm signal is predicted given a set of 7 input parameters. The complete prediction algorithm is summarized in Fig. 13 and contains the following steps:

(i) Given the seven input astrophysical parameters \( [V_c, f_X, \tau, \nu_{\text{min}}, R_{\text{adp}}, f_{\text{X11}}, f_{\text{X12}}] \) the algorithm calculates five auxiliary parameters \( f_{\text{X11}}, f_{\text{X12}}, f_{\text{X13}}, f_{\text{X14}}, f_{\text{X15}} \). A trained NN (Sec. 2.3) is used to infer the value of the ionizing efficiency \( \zeta \) given the input \( \tau \).

(ii) Using the full set of parameters the algorithm verifies whether this case has a valid EoR history or not (as described in Sec. 2.4).

(iii) If the case is valid, the algorithm uses decision trees to classify the case and determines if it is expected to have an emission feature or not (i.e., whether the case is negative or positive, Sec. 4.1.1).

(iv) Based on the input parameters, NNs (Sec. 4.1.3) predict the PCA coefficients for each of the segments as well as the coordinates of the key astrophysical points (as explained in Sec. 4.1.2).

(v) A coordinate transformation (inverse of Eq. 9) is performed to return the signal in physical units of mK as a function of frequency in MHz.

### 5 SUMMARY AND CONCLUSIONS

In this paper we have presented a database of 29,641 global 21-cm signals generated over the widest possible space of seven astrophysical parameters that include the star formation efficiency, minimum cooling mass, X-ray radiation efficiency, the slope and the low energy cut-off of the X-ray spectrum, the mean free path of the ionizing photons, and the CMB optical depth. The parameter space is constrained by the observations of the CMB and quasar absorption lines as well as by the maximum possible ionizing efficiency (corresponding to massive metal-free stars).

We used this dataset to verify the consistency relations between the astrophysical parameters and the properties of

\[ V_c, f_X, \tau, \nu_{\text{min}}, R_{\text{adp}} \]
Table 1. Accuracy in prediction of the key points $\nu_{\text{hi}}^\text{max}$, $T_{\text{hi}}^\text{max}$, $\nu_{\text{min}}$, $T_{\text{min}}$, $\nu_{\text{lo}}^\text{max}$, $T_{\text{lo}}^\text{max}$ and $\nu_{\text{reion}}$. The percentage of cases with a relative error below 2% (5%) in the prediction is shown in the second (third) row.

| Key point | $\nu_{\text{hi}}^\text{max}$ | $T_{\text{hi}}^\text{max}$ | $\nu_{\text{min}}$ | $T_{\text{min}}$ | $\nu_{\text{lo}}^\text{max}$ | $T_{\text{lo}}^\text{max}$ | $\nu_{\text{reion}}$ |
|-----------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Prediction error below 2% [%] | 97.44 | 99.59 | 77.02 | 78.88 | 66.88 | 38.54 | 96.68 |
| Prediction error below 5% [%] | 100 | 100 | 99.42 | 98.28 | 98.57 | 59.87 | 99.88 |

Figure 12. Left panel: Predicted versus true value of the amplitude of the absorption feature, shown for 1,743 cases. Also shown is the perfect prediction ($Y = X$, solid red line). Right panel: Histogram of the relative error in the predicted amplitude of the absorption trough.

the global 21-cm signal first reported in our previous paper (Cohen et al. 2017), finding a good agreement in all relations except for the value of $J_\alpha/\epsilon$ at $z_{\text{min}}$ which shows much larger scatter due to the wider selection of X-ray spectra considered here. In particular, there remains a tight predicted relationship between the brightness temperature and the observed frequency of the high-redshift maximum point (Fig. 6); a measurement of this point can be used to infer the Ly$\alpha$ intensity at that time, though with significant scatter (Fig. 7). Also, the brightness temperature and observed frequency of the low-redshift maximum point follow a tight relation, which can be used to estimate the X-ray intensity (Fig. 9).

We utilized the database to develop and test 21cmGEM which, given a set of astrophysical parameters, predicts the global 21-cm signal. Additional outputs include values of the neutral fraction at $z = 5.9$, $z = 7.08$ and $z = 7.54$ along with frequencies at which the neutral fraction is 0.16% and 11%. The crucial elements of the emulator are:

(i) Smoothness of the output signal is guaranteed by construction.

(ii) The database can be divided into two categories: signals that have an emission feature and signals that are only seen in absorption. The classification is done using bagged decision trees.

(iii) We train neural networks to predict the cosmological signal based on the seven astrophysical parameters. Each signal is broken into a few segments separated by the key astrophysical points and is decomposed into a basis of smooth orthogonal functions using PCA. Because PCA ranks the eigenfunctions by variance in decreasing order, most of the information is encoded in the first few terms. This allows us to reduce the dimensionality and use only the first four functions of the basis. Neural networks are used to predict the PCA coefficients as well as the two ends of each segment given a set of astrophysical parameters.

(iv) The algorithm also checks whether the case satisfies current constraints on reionization. The constraints that are taken into account include limits on the total CMB optical depth, the upper limit on the ionization efficiency of stars, and the upper limit on the neutral fraction at $z \sim 5.9$ derived from the absorption profile of high-redshift quasars. Using these conditions the minimum circular velocity of star-forming halos as well as the star formation efficiency can be constrained. We find a lower limit of $V_c \sim 26$ km s$^{-1}$ ($\sim 4 \times M_{\text{atomic}}^{\text{min}}$) for an optical depth of 0.055.

The algorithm was trained on 27,455 simulated signals, and an additional 2,186 cases were used as the test set. The predicted signal has an r.m.s. error of 0.0159, corresponding to 1.59% of the signal amplitude, with 98.9% of cases having errors lower than 0.05. The algorithm is efficient, with running time per parameter set of 0.16 sec. This tool can be used in the fitting process (e.g., MCMC) to constrain the high-redshift parameter space using the data of global signal experiments. We have used it recently with the data from EDGES High-Band (Monsalve et al. 2019). 21cmGEM and the training and testing datasets are available online at https://www.ast.cam.ac.uk/~afialkov/.

© 2018 RAS, MNRAS 000, 1–16
Figure 13. Flowchart of the prediction process as outlined in Sec. 4.2.
Figure 14. Histogram of the errors in the predicted global 21-cm signals, normalized by their maximum amplitude, as defined in Eq. 11. The results are shown for the entire test set of 1,743 cases.

6 ACKNOWLEDGMENTS

We acknowledge the usage of the Harvard Odyssey cluster. Part of this project was supported by the Royal Society University Research Fellowship of AF. RB and AC acknowledge Israel Science Foundation grant 823/09 and the Ministry of Science and Technology, Israel. This project/publication was made possible for RB through the support of a grant from the John Templeton Foundation. The opinions expressed in this publication are those of the authors and do not necessarily reflect the views of the John Templeton Foundation.
