Abstract

Using out-of-band (OOB) side-information has recently been shown to accelerate beam selection in single-user millimeter wave (mmWave) massive MIMO (m-MIMO) communications. In this paper, we propose a novel OOB-aided beam selection framework for a mmWave uplink multi-user system. In particular, we exploit spatial information extracted from lower (sub-6 GHz) bands in order to assist with an inter-user coordination scheme at mmWave bands. To enforce coordination, we propose an exchange protocol exploiting device-to-device (D2D) communications. In particular, low-rate beam-related information is exchanged between the mobile terminals. The decentralized coordination mechanism allows the suppression of the so-called co-beam interference which would otherwise lead to irreducible interference at the base station (BS) side, thereby triggering substantial spectral efficiency (SE) gains.

I. INTRODUCTION

The large bandwidths available at mmWave carrier frequencies are expected to help meet the throughput requirements for future mobile networks [1]. In order to guarantee appropriate link margins and coverage in response to stronger path losses [2], m-MIMO antennas are expected to be used at both BS and UE sides (when the form factor allows). However, configuring those antennas entails an additional effort. The high cost and power consumption of the radio components impact on the UEs and small BSs, thus limiting the practical implementation of a fully-digital beamforming architecture [1]. As a consequence, mixed analog-digital (hybrid) architectures have been proposed [3], where a low-dimensional digital processor is concatenated with an RF analog beamformer, implemented through phase shifters [1].

Interestingly, most works on such architectures opt to leave aside multi-user interference issues in the analog domain and cope with them in the digital part instead. For instance, in [4], the
analog stage is intended to find the best beam directions at each UE regardless of the fact that resulting paths arriving at the BS from different UE might end up in the same receive BS analog beam (so-called co-beam interference). The strength of this approach lies in the fact that it is possible to use the existing beam training algorithms for single-user links – such as [5]–[7] – in the analog stage. Such algorithms have been developed bearing in mind the need for fast link establishment in mmWave communications [8]. Yet, multiple closely-located UEs bear certain risk to share one or more common reflectors, causing the potential alignment of some strong paths’ angles of arrival (AoA) at the BS [2]. In this case, the application of the Zero-Forcing (ZF) criterion on the resulting effective channel in the digital domain might not be effective.

To solve the irreducible uplink co-beam interference problem, a possible approach consists in addressing the interference before it takes place, i.e. the UE side, as is done e.g. in [9]. Although showing significant gains over the existing solutions, such works assume perfect CSI for analog beamforming, which might not be realistic in some mmWave contexts [4].

To go around this problem, we propose a UE coordination mechanism exploiting statistical OOB information. Several prior works have pioneered the idea of exploiting side-information (in particular, extracted from sub-6 GHz bands) for mmWave performance optimization [5]–[7], but – to our best knowledge – not in the multi-user setting. The coordination mechanism is based on the idea of each UE autonomously selecting an analog beam for transmission so as to strike a trade-off between (i) capturing enough channel gain and (ii) ensuring the UE signals impinge on distinct beams at the BS side. The intuition behind point (ii) is to ensure that the effective channel matrix seen by the BS preserves full rank properties, thus enabling inter-UE interference mitigation in the digital domain.

In this paper, further novelty originates from (i) the way OOB-based side-information is exploited to enable a coordination mechanism between the UEs, and the fact that (ii) not all the UEs need to be endowed with the same amount of side-information. In particular, our scheme leverages a hierarchical information exchange which allows halving of the overall information overhead compared with a full exchange scenario. In this setup, some higher ranked UEs receive sub-6 GHz beam information from lower ranked ones only. This configuration can be obtained through e.g. D2D communications. In this respect, the 3GPP Release 16 is expected to support point-to-point side-links which facilitate cooperative communications among the UEs with low resource consumption [10].
II. SYSTEM MODEL AND PROBLEM FORMULATION

We consider a multi-band scenario, where a conventional wireless network using sub-6 GHz bands coexists with a mmWave one. In the following, we introduce the mmWave model. In line with [7], the sub-6 GHz model is likewise defined, with all variables underlined to distinguish them.

A. Uplink Millimeter Wave Model

The BS is equipped with $N_{BS} \gg 1$ antennas to support $K$ UEs with $N_{UE} \gg 1$ antennas each. The UEs are assumed to reside in a disk of radius $r$, which will be used to control inter-UE average distance. To ease the notation, we assume that the BS has $K$ RF chains available (one for each UE), connected to all the $N_{BS}$ antennas (fully-connected [1] hybrid architecture [1]).

The $u$-th UE precodes the data $x^u \sim \mathcal{C}\mathcal{N}(0, 1)$ with the analog unit norm vector $v^u \in \mathbb{C}^{N_{UE} \times 1}$. We assume that the UEs have one RF chain each, i.e. UEs are limited to analog beamforming via phase shifters (constant-magnitude elements) [3]. In addition, $\mathbb{E}[\|v^u x^u\|^2] \leq 1$, assuming normalized power constraints. The reconstructed signal after mixed analog/digital combining at the BS is expressed as follows – assuming no timing and carrier mismatches:

$$\hat{x} = W_D \sum_{u=1}^{K} W_{RF}^H H^u v^u x^u + W_D W_{RF}^H n$$  \hspace{1cm} (1)

where $H^u \in \mathbb{C}^{N_{BS} \times N_{UE}}$ is the channel matrix from the $u$-th UE to the BS, $n \sim \mathcal{C}\mathcal{N}(0, \sigma_n^2 I)$ is the thermal noise vector, $W_{RF} \in \mathbb{C}^{N_{BS} \times K}$ contains the beamformers relative to each RF chain (subject to the same hardware constraints as described above), and $W_D \in \mathbb{C}^{K \times K}$ denotes the digital combining matrix.

Introducing the effective channel $h^u_e = W_{RF}^H H^u v^u \in \mathbb{C}^{K \times 1}$ of the $u$-th UE, we can write (1) as follows:

$$\hat{x} = W_D \sum_{u=1}^{K} h^u_e x^u + W_D \tilde{n} = W_D H_e x + W_D \tilde{n}$$  \hspace{1cm} (2)

where $H_e \in \mathbb{C}^{K \times K}$ denotes the effective channel matrix – containing all the single effective channels – and where $\tilde{n} = W_{RF}^H n$ denotes the filtered thermal noise vector.

Although partially-connected architectures are more relevant for practical implementation due to less stringent hardware requirements [11], we assume fully-connected architectures to keep notation light, as in most prior works focusing on mmWave SE maximization, e.g. [3], [4], [9]. The beam selection strategies which we will propose in Section [III] are in principle extendible to all mixed analog/digital beamforming architectures.
Fig. 1: Co-beam interference example with $C = 3$ clusters, $L = 2$ paths, and $K = 2$ UEs. The UEs are assumed to reside in a disk of radius $r$. In this illustration, two closely-located UEs share some reflectors and the signal waves reflecting on the top ones arrive quasi-aligned at the BS – i.e. captured with the same BS beam – while originating from distinct UEs.

### B. Channel Model

Assuming mmWave channels exhibit limited scattering [2], we adopt a geometric narrow-band channel model with $C$ clusters, each one contributing to $L$ paths. The channel matrix $H^u \in \mathbb{C}^{N_{BS} \times N_{UE}}$ for the $u$-th UE is thus expressed as follows [7]:

$$H^u \triangleq \sqrt{N_{BS} N_{UE}} \left( \sum_{c=1}^{C} \sum_{\ell=1}^{L} \alpha_{c,\ell}^u a_{BS}(\theta_{c,\ell}^u) a_{UE}^H(\phi_{c,\ell}^u) \right)$$

where $\alpha_{c,\ell}^u \sim \mathcal{CN}(0, \sigma_c^2)$ denotes the complex gain for the $\ell$-th path of the $c$-th cluster of the $u$-th UE, including the shaping filter and the large-scale pathloss. The variables $\phi_{c,\ell}^u \in [0, 2\pi)$ and $\theta_{c,\ell}^u \in [0, 2\pi)$ are the AoD and AoA for the $\ell$-th path of the $c$-th cluster connecting the $u$-th UE to the BS. The vectors $a_{UE}(\cdot) \in \mathbb{C}^{N_{UE} \times 1}$ and $a_{BS}(\cdot) \in \mathbb{C}^{N_{BS} \times 1}$ denote the antenna unitary steering vectors at the $u$-th UE and the BS, respectively. We assume uniform linear arrays (ULA) with $\lambda/2$ inter-element spacing.
C. Analog Codebooks

We define the codebooks used for analog beamforming as

\[ V \triangleq \{ v_1, \ldots, v_{M_{\text{UE}}} \}, \quad W \triangleq \{ w_1, \ldots, w_{M_{\text{BS}}} \} \tag{4} \]

where \( M_{\text{UE}} = N_{\text{UE}} \) and \( M_{\text{BS}} = N_{\text{BS}} \) denote the number of elements (beamforming vectors) in the codebooks, and where \( V \) is assumed to be shared between all the UEs, to ease the notation.

For instance, with ULA, a suitable design for the fixed elements in the codebook consists in selecting steering vectors over a discrete grid of angles, as follows [4]:

\[ v_n = a_{\text{UE}}(\hat{\phi}_n), \quad n \in [1, M_{\text{UE}}] \tag{5} \]
\[ w_m = a_{\text{BS}}(\hat{\theta}_m), \quad m \in [1, M_{\text{BS}}] \tag{6} \]

where the quantized angles \( \hat{\phi}_n \) and \( \hat{\theta}_m \) can be chosen according to different sampling strategies of the \([0, \pi]\) range [5].

Remark 1. The notation \([1, M]\) denotes the set \([1, \ldots, M]\). The same notation will be used in the remainder of the paper.

D. Problem Formulation

The beam selection problem in mmWave communications consists in selecting the analog transmit and receive beams from \( V \) and \( W \) to maximize the sum-rate defined as follows:

\[ R(n, m) \triangleq \sum_{u=1}^{K} \log_2 \left( 1 + \gamma^u(n, m) \right) \tag{7} \]

where \( n \triangleq [n_1 \ldots n_K] \) (resp. \( m \triangleq [m_1 \ldots m_K] \)) is the vector containing the selected beams at the UE (resp. BS side), while \( \gamma^u \) is the received SINR for the \( u \)-th UE, defined as [4]

\[ \gamma^u(n, m) \triangleq \frac{|w^u_D h^u_e|^2}{\sum_{w \neq u} |w^u_D h^w_e|^2 + |w^u_D|^2 \sigma_n^2} \tag{8} \]

with \( w^u_D \in \mathbb{C}^{1 \times K} \) denoting the \( u \)-th row of \( W_D \).

In order to maximize (7), the mutual optimization of both analog and digital components must be considered. A common viable approach consists in decoupling the design, as the analog precoder can be optimized through long-term statistical information, whereas the digital one can be made dependent on instantaneous one [4]. The same approach is followed here.

In particular, we consider ZF combining, so that we have

\[ W_D = \left( H_e^H H_e \right)^{-1} H_e^H. \tag{9} \]
The received SINR for the $u$-th UE is then simplified as

$$\gamma^u(n,m) = \frac{1}{\sigma_n^2 \{ (H_e^H H_e)^{-1} \}_{u,u}}$$

with $\{ \cdot \}_{u,u}$ denoting the $u$-th element on the diagonal of $(H_e^H H_e)^{-1}$, associated to the $u$-th UE.

In general, the perfect knowledge of the effective channels plus a centralized operator to instruct the UEs are needed to maximize (7) via (10). Such information is not available without a significant resource overhead. In the next section, we propose some strategies to exploit sub-6 GHz information for a distributed and low-overhead approach to the problem.

III. OUT-OF-BAND-AIDED BEAM SELECTION

Let us consider the existence of a sub-6 GHz channel $H^u \in \mathbb{C}^{N_{\text{BS}} \times N_{\text{UE}}}$ between the $u$-th UE and the BS. We assume that each UE is able to compute a spatial spectrum $\mathbb{E}[|S^u|^2] \in \mathbb{C}^{M_{\text{BS}} \times M_{\text{UE}}}$ of the sub-6 GHz channel, where

$$S^u = W^H H^u V$$

and where the expectation is over fast fading. The matrices $W \in \mathbb{C}^{N_{\text{BS}} \times M_{\text{BS}}}$ and $V \in \mathbb{C}^{N_{\text{UE}} \times M_{\text{UE}}}$ collect all the sub-6 GHz steering vectors at the BS and UE sides, sampled at the same angles as the mmWave ones. In particular, we assume $N_{\text{BS}} \ll M_{\text{BS}} = M_{\text{BS}}$ and $N_{\text{UE}} \ll M_{\text{UE}} = M_{\text{UE}}$. The $(m,n)$-th element of $\mathbb{E}[|S^u|^2]$ contains thus the sub-6 GHz channel gain obtained with the $n$-th beam at the $u$-th UE and the $m$-th one at the BS.

Remark 2. The computation of $\mathbb{E}[|S^u|^2]$ is merely bound to the knowledge of the average sub-6 GHz channel, as $W$ and $V$ are predefined fixed matrices. Note that the acquisition of the CSI matrix for conventional sub-6 GHz communications is a standard operation [12]. In this respect, sub-6 GHz channel measurements can be collected and stored periodically – e.g. within the channel coherence time – to be readily available for evaluating $\mathbb{E}[|S^u|^2]$. In other words, obtaining the spatial spectrum $\mathbb{E}[|S^u|^2]$ requires no additional training overhead [7].

A. Exploiting Sub-6 GHz Information

The available sub-6 GHz spatial information can be exploited to obtain a rough estimate of the angular characteristics of the mmWave channel. Indeed, due to the larger beamwidth of sub-6 GHz beams, one sub-6 GHz beam can be associated to a set of mmWave beams, as defined below.
Definition 1. For a given sub-6 GHz beam pair \((n_\bar{m}, m_\bar{m})\), we introduce the set \(S(n_\bar{m}, m_\bar{m}) \triangleq S_{\text{UE}}(n_\bar{m}) \times S_{\text{BS}}(m_\bar{m})\) where \(S_{\text{UE}}(n_\bar{m})\) (resp. \(S_{\text{BS}}(m_\bar{m})\)) contains all the mmWave beams belonging to the 3-dB beamwidth of the \(n\)-th (resp. \(m\)-th) sub-6 GHz beam.

It is important to remark that we focus in this work on the selection of sub-6 GHz beams to further refine. We indeed adhere to the well-known two-stage beamforming and training operation, where fine-grained training (called beam refinement) follows coarse-grained training (called sector sweeping). In our approach, coarse-grained beam selection is achieved without actually training the beams with reference signals, but using instead beam information extracted from lower channels, so as to speed up the process. Once these coarse sub-6 GHz beams are chosen, the small subset of associated mmWave beams is trained. We refer to [13] for more details on this standard step. In what follows, we propose some multi-user beam selection strategies leveraging the described OOB-related side-information.

B. Uncoordinated Beam Selection

We first describe here an approach based on [4], where the authors proposed to design the analog beamformers so as to maximize the received power (SNR) for each UE, neglecting multi-user interference. When OOB information is available, the beam selection \((n^u_\bar{m}, m^u_\bar{m})\) at the \(u\)-th UE – which we will denote as uncoordinated (un) – can be expressed as follows:

\[
(n^u_\bar{m}, m^u_\bar{m}) = \arg \max_{n_\bar{m}, m_\bar{m}} \log_2 \left( 1 + \mathbb{E}_{n_\bar{m}, m_\bar{m} | n^u_\bar{m}, m^u_\bar{m}} \left[ \gamma^u_{su}(n^u_\bar{m}, m^u_\bar{m}) \right] \right)
\]  
(12)

where we have approximated the rate via Jensen’s inequality and we have defined the single-user expected SNR, conditioned on a given sub-6 GHz beam pair \((n^u_\bar{m}, m^u_\bar{m})\) \(\in \mathcal{V} \times \mathcal{W}\), as follows:

\[
\mathbb{E}_{n_\bar{m}, m_\bar{m} | n^u_\bar{m}, m^u_\bar{m}} \left[ \gamma^u_{su}(n^u_\bar{m}, m^u_\bar{m}) \right] = \sum_{(n_\bar{m}, m_\bar{m}) \in S(n^u_\bar{m}, m^u_\bar{m})} \frac{g_{n^u_\bar{m}, m^u_\bar{m}}}{S_u \sigma^2_n}
\]  
(13)

with

\[
g_{n^u_\bar{m}, m^u_\bar{m}} \triangleq \mathbb{E} \left[ |w^u_{m^u_\bar{m}} H^u_{n^u_\bar{m}} v^u_{n^u_\bar{m}}|^2 \right]
\]  
(14)

\[
= \mathbb{E} \left[ |S^u_{n^u_\bar{m}, m^u_\bar{m}}|^2 \right]
\]  
(15)

being the average beamforming gain obtained at the \(u\)-th UE with the transmit-receive beam pair \((n^u_\bar{m}, m^u_\bar{m})\), and where \(S_u \triangleq \text{card}(S(n^u_\bar{m}, m^u_\bar{m}))\).
To solve (13), the $u$-th UE needs to know the mmWave gain $g_{n_u,m_u}$ $\forall (n_u,m_u) \in \mathcal{S}(n_u,m_u)$. This information is not available but can be replaced for algorithm derivation purposes\(^2\) with the gain observed in the sub-6 GHz channel over the beam pair $(n_u,m_u)$. In other words, we assume
\[
g_{n_u,m_u} \approx \mathbb{E} \left[ |S_{n_u,m_u}^u|^2 \right] \quad \forall (n_u,m_u) \in \mathcal{S}(n_u,m_u). \tag{16}
\]

Note that the average gain information derived from $\mathcal{S}$ will unlikely match with its mmWave counterpart in absolute terms practice, due to multipath, noise effects and pathloss discrepancies. Still, high correlation has been observed between the temporal and angular characteristics of the LOS path in sub-6 GHz and mmWave channels\(^1\). The correlation diminishes as the LOS condition is lost, as small scattering objects participating in the radio propagation emerge at higher frequencies\(^5\). Nevertheless, it has been shown in\(^5\) that, in an outdoor scenario with strong reflectors (buildings), the paths with uncommon AoA at frequencies far apart\(^3\) are less than 10\% of the overall paths. In this respect, (16) allows to spot a valuable candidate set for mmWave beams in most of the situations. Yet, an important limitation of this approach is that each UE solves its own beam selection problem independently of the other UEs, thus ignoring the possible impairments in terms of interference. Therefore, as the inter-UE average distance decreases, the performance of this procedure degrades since the UEs have much more chance to share their best propagation paths – which results in co-beam interference at the BS.

### C. Hierarchical Coordinated Beam Selection

In order to achieve coordination, we propose to use a hierarchical information structure requiring small overhead. In particular, an (arbitrary) order among the UEs is established\(^4\) for which the $u$-th UE has access to the beam decisions carried out at the (lower-ranked) UEs $1,...,u-1$. This configuration is obtainable through e.g. dedicated D2D channels in the lower bands\(^5\). We further assume that such exchanged beam information is perfectly decoded at the intended UEs.

\(^2\)The proposed algorithms are then evaluated in Section IV under realistic multi-band channel conditions as proposed in\(^7\), where the described behavior and consequent randomness is taken into account.

\(^3\)In\(^5\), 5 carrier frequencies ranging between 900 MHz and 90 GHz have been compared.

\(^4\)The hierarchical information exchange is proposed here to facilitate the coordination mechanism at reduced overhead. In this paper, we shall leave aside further analysis on how such a hierarchy is defined and maintained.

\(^5\)D2D communications allows to exchange information among closely-located UEs with low resource (power, time, etc.) consumption\(^17\). In particular, the power consumption for exchanging low-rate beam information over D2D side-links could be negligible due to the small relative path loss as compared to communicating to the BS.
Since the UEs exchange beam indexes (in the order of few bits), the communication overhead is kept low. Moreover, the so-called beam coherence time – which depends on beam width and UE speed among others – has been reported to be much longer than the channel coherence time [18]. As a consequence, such overhead is only generated at long intervals.

**Remark 3.** Exchanging sub-6 GHz beams rather than mmWave ones introduces some uncertainty, but allows to save time as no UE has to wait for another one to perform beam training. □

Assuming that the sub-6 GHz beam indices \( \eta_{1,\ldots,u-1} \) have been received, the *coordinated* (co) sub-6 GHz beam pair \( (\eta_u, \eta_u) \in \mathcal{V}, (\eta_u, \eta_u) \in \mathcal{W} \) at the \( u \)-th UE is obtained through

\[
(\eta_u, \eta_u) = \text{argmax}_{u, \eta_u} \log_2 \left( 1 + \mathbb{E}_{n,m,\eta_{u+1,\ldots,u}} \left[ \gamma_u(n,m) \right] \right).
\] (17)

Solving (17) is not trivial, being a subset selection problem for which a Monte-Carlo approach to approximate the expectation with a discrete summation leads to unpractical computational time. Interestingly, for large \( N_{BS} \) and \( N_{UE} \), we are able to derive an approximation for the expectation in (17) which will be useful for algorithm derivation. We start with showing such intermediate result.

**Proposition 1.** In the limit of large \( N_{BS} \) and \( N_{UE} \), the expected SINR (averaged over small-scale fading) of the \( u \)-th UE obtained after ZF combining at the BS is

\[
\mathbb{E} \left[ \gamma_u(n,m) \right] = \begin{cases} 
\frac{g_{n,\eta_u} m_u}{\sigma_n^2} & \text{if } m_u \neq m_w \forall w \in \mathcal{K}\backslash\{u\} \\
0 & \text{if } \exists w \in \mathcal{K}\backslash\{u\} : m_w = m_u
\end{cases}
\] (18)

where we have defined \( \mathcal{K} \triangleq [1,K] \).

**Proof.** Based on the result in [19], we assume that the quantized angles \( \hat{\phi}_n, n \in [1,M_{UE}] \) and \( \hat{\theta}_m, m \in [1,M_{BS}] \) are spaced according to the inverse cosine function. The following lemma states an interesting consequence (constant inner product) of such a spacing which will be useful later.

**Lemma 1.** Let the angles \( \hat{\phi}_n \) and \( \hat{\theta}_m \) be spaced according to the inverse cosine function, as follows:

\[
\hat{\phi}_n = \arccos \left( 1 - \frac{2(n-1)}{M_{UE}-1} \right), \quad n \in [1,M_{UE}]
\]

\[
\hat{\theta}_m = \arccos \left( 1 - \frac{2(m-1)}{M_{BS}-1} \right), \quad m \in [1,M_{BS}]
\] (19)

then

\[
\begin{align*}
\mathbf{a}_\text{UE}^H(\hat{\phi}_n) \mathbf{a}_\text{UE}(\hat{\phi}_n) &= 1/N_{UE} \\
\mathbf{a}_\text{BS}^H(\hat{\theta}_m) \mathbf{a}_\text{BS}(\hat{\theta}_m) &= 1/N_{BS}
\end{align*}
\] (20)

for any \( n \neq \tilde{n} \) and \( m \neq \tilde{m} \).
Proof of Lemma 1. In the following, we will consider w.l.o.g. the UE side.

Let \( \Delta \triangleq \cos(\hat{\phi}_n) - \cos(\hat{\phi}_{\tilde{n}}) \), then we have:

\[
a_{\text{UE}}^H(\hat{\phi}_n)a_{\text{UE}}(\hat{\phi}_{\tilde{n}}) = \frac{1}{N_{\text{UE}}} \sum_{k=0}^{N_{\text{UE}}-1} e^{-i\pi k \Delta} \tag{21}\]

\[
(a) \quad \frac{1}{N_{\text{UE}}} \frac{1-e^{-i\pi N_{\text{UE}} \Delta}}{1-e^{-i\pi \Delta}} \tag{22}\]

where \((a)\) is due to geometric series properties.

According to the spacing in (19), we can write \( \Delta = \frac{2(\tilde{n} - n)}{N_{\text{BS}} - 1} \). Inserting this expression in (21) gives:

\[
a_{\text{UE}}^H(\hat{\phi}_n)a_{\text{UE}}(\hat{\phi}_{\tilde{n}}) = \frac{1}{N_{\text{UE}}} \frac{e^{i\pi \Delta} - e^{-i\pi (\tilde{n} - n)}}{e^{i\pi \Delta} - 1} \tag{23}\]

\[
(b) \quad \frac{1}{N_{\text{UE}}} \tag{24}\]

where \((b)\) follows from \(2\pi (\tilde{n} - n) = 0 \pmod{2\pi}\) for \( \tilde{n} \neq n \).

According to Lemma 1 in the limit of large \( N_{\text{BS}} \) and \( N_{\text{UE}} \), \( a_{\text{UE}}(\hat{\phi}_n) \perp \text{span}(a_{\text{UE}}(\hat{\phi}_{\tilde{n}}) \forall \tilde{n} \neq n) \). Likewise \( a_{\text{BS}}(\hat{\theta}_m) \perp \text{span}(a_{\text{BS}}(\hat{\theta}_{\tilde{m}}) \forall \tilde{m} \neq m) \). As a consequence, the matrices

\[
\hat{A}_{\text{BS}} = \begin{bmatrix} a_{\text{BS}}(\hat{\theta}_1) & \ldots & a_{\text{BS}}(\hat{\theta}_{M_{\text{BS}}}) \end{bmatrix}, \tag{25}\]

and

\[
\hat{A}_{\text{UE}} = \begin{bmatrix} a_{\text{UE}}(\hat{\phi}_1) & \ldots & a_{\text{UE}}(\hat{\phi}_{M_{\text{UE}}}) \end{bmatrix} \tag{26}\]

are asymptotically unitary. To go further, we resort to the channel approximation in [20], which consists in approximating the channel given in (3) using the quantized angles, as follows:

\[
H^u \approx \sqrt{N_{\text{BS}}N_{\text{UE}}} \sum_{n=1}^{M_{\text{UE}}} \sum_{m=1}^{M_{\text{BS}}} \psi_{n,m}^u a_{\text{BS}}(\hat{\theta}_m)a_{\text{UE}}^H(\hat{\phi}_n) \tag{27}\]

where \( \psi_{n,m}^u \) is equal to the sum of the gains of the paths whose angles lie in the virtual spatial bin centered on \((\hat{\phi}_n, \hat{\theta}_m)\).

We rewrite now (10) using the Schur complement as follows:

\[
\gamma^u(n,m) = \frac{1}{\sigma_{\tilde{n}}^2} \left[ (h_c^u)^H h_c^u - (h_c^u)^H P_{e/u} h_c^u \right] \tag{28}\]

where \( P_{e/u} \triangleq H_{c/u}(H_{c/u}^H H_{c/u})^{-1} H_{c/u}^H \) is the orthogonal projection onto the span\((H_{c/u})\), with \( H_{c/u} \) being the submatrix obtained via removing the \( u \)-th column from \( H_c \).
Since $\hat{A}_{\text{UE}}$ and $\hat{A}_{\text{BS}}$ are asymptotically unitary, it holds that

$$P_{e/u} h^u_c = \begin{cases} 0 & \text{if } m_u \neq m_w \ \forall w \in \mathcal{K}\{u\} \\ h^u_c & \text{if } \exists w \in \mathcal{K}\{u\} : m_w = m_u \end{cases}$$

and, as a consequence, equation (28) becomes

$$\gamma^u(n, m) = \begin{cases} \|h^u_c\|^2 / \sigma^2_n & \text{if } m_u \neq m_w \ \forall w \in \mathcal{K}\{u\} \\ 0 & \text{if } \exists w \in \mathcal{K}\{u\} : m_w = m_u \end{cases}$$

whose expected value is as (18), which concludes the proof.

**Remark 4.** In the large-dimensional regime, the dependence of the SINR in (8) on the transmit beams of the other UEs vanishes. In particular, catastrophic co-beam interference is experienced through intersections at the BS receive beam *only*. We kept the dependence in (18) to avoid introducing additional notation.

Using Proposition 1, the expectation in (17) can be approximated as follows:

$$E_{n,m|y_u, m_1, \ldots, u} [\gamma^u(n, m)] \approx \sum_{(n_u, m_u) \in S(y_u, m_u)} \sum_{m_u \neq m_i} S_u \sigma^2_n$$

Using (31) in (17) to choose the sub-6 GHz beams at the $u$-th UE allows to take into account the potential co-beam interference transferred to the lower-ranked UEs with low complexity.

**Remark 5.** The $K$-th (highest-ranked) UE has to consider via (31) the coarse-grained beam decisions of all the other (lower-ranked) UEs to avoid generating potential co-beam interference. Therefore, such UE might be forced to exchange high data rate for less leakage, as the best non-interfering paths might have been already exploited. Therefore, it is essential to *change the hierarchy* at regular intervals to ensure an average acceptable rate per UE.

We summarize the proposed coordinated beam selection in Algorithm 1. The algorithm is compatible with vectorization and parallelization, which minimize computational time.

**IV. Simulation Results**

We evaluate here the performance of the proposed algorithm for $K = 5$ closely-located UEs. We assume $N_{\text{BS}} = 64$, $N_{\text{UE}} = 16$ for mmWave communications, and $N_{\text{BS}} = 8$ and $N_{\text{UE}} = 4$ for sub-6 GHz ones. As for the carrier frequencies, we consider 28 GHz and 3 GHz for mmWave and sub-6 GHz operation, respectively. All the plotted data rates are the averaged – over 10000 Monte-Carlo iterations – instantaneous sum-rates, obtained after ZF combining at the digital stage (BS side).
Algorithm 1 OOB-Aided Hierarchical Coordinated Beam Selection at the generic $u$-th UE

INPUT: $E\left[|S^u|^2\right]$, $\bar{y}_1, ..., \bar{y}_{u-1}$

Step 1: Exploiting OOB side-information

1: if $u = 1$ then \>	ext{The $u$-th UE is the lowest in the hierarchy}
2: $E[\gamma^u] = E\left[|S^u|^2\right]/\sigma^2_{\bar{n}}$ \>	ext{Solve (12) via (13)}
3: else \>	ext{The $u$-th UE is not the lowest in the hierarchy}
4: for $n = 1 : M_{UE}$ do
5: \quad for $m = 1 : M_{BS}$ do
6: \quad \quad $N = \text{card}\left( S(n,m) \setminus S_{BS}(m_1) \cup \cdots \cup S_{BS}(m_{u-1}) \right)$
7: \quad \quad $S = \text{card}\left( S(n,m) \right)$
8: \quad $T = E\left[|S^u_{n,m}|^2\right]/\sigma^2_{\bar{n}}$
9: \quad $E[\gamma^u(n,m)] = NT/S$ \>	ext{Solve (17) via (31)}
10: \quad end for
11: end for
12: end if
13: return $(\bar{y}^c_u, \bar{y}^c_u) \leftarrow \text{argmax}_{0,m} E[\gamma^u]$

Step 2: Pilot-training the subset of mmWave beams

14: $(\bar{y}^c_u, \bar{y}^c_u) \leftarrow \text{argmax}_{n,m} \left| w_m^u H^u v_n^u \right|^2 \forall n,m \in S(\bar{y}^c_u, \bar{y}^c_u)$

A. Multi-Band Channels

The performance of the proposed OOB-aided algorithms depends on the spatial congruence between sub-6 GHz and mmWave channels. The authors in [7] proposed a simulation environment for generating sub-6 GHz and mmWave channels based on the model in (3). The MATLAB\textsuperscript{®} code used to simulate those channels is open-source and available on IEEEXplore [7]. We use the same model except that we consider a narrowband channel model, for which path time spread and beam squint effect can be neglected [2]. Note that frequency-selective filters at the BS side helps discriminating (in time) among UEs which generate co-beam interference, and thus might results in giving an extra performance in average wideband channels. In this paper, we consider a worst case scenario to present the substance of our idea. In principle, models and algorithms could be extended to a wideband setting.
B. Results and Discussion

We consider a stronger (on average) LOS cluster with respect to the reflected ones, as the LOS is indeed the prominent propagation driver in mmWave bands [2]. In particular, we adopt the following large-scale pathloss model:

\[
PL(\delta) = \alpha + \beta \log_{10}(\delta) + \xi \quad [\text{dB}]
\]  

(32)

where \(\delta\) is the path length and where the pathloss parameters \(\alpha, \beta\) and \(\xi\) are taken from Table 1 in [2] for both LOS and NLOS contributions. The large-scale pathloss is then reflected in the cluster power \(\sigma_c^2\) \(\forall c\). The average power of all the paths in a given cluster is assumed to be equal. Since the model in [7] is for a single-user scenario, we consider the model in [21] to extend it so as to generate correlated channel clusters for all the neighboring UEs in the disk. In [21], the position of the clusters is made also dependent on the position of the UEs, and as a result, the possible sharing of reflectors and scatterers for neighboring UEs is taken into account. An example of the available sub-6 GHz spatial spectrum at two UEs is shown in Fig. 2.

![Fig. 2: Example of available \(E[|S_u|^2]\) at two neighboring UEs, with \(r = 11\) m. Some reflectors are being shared, while others are uncommon. The average path gains can be different.](image-url)
In Fig. 3, we show the sum-rate of the proposed algorithms as a function of the SNR, where the average distance between the UEs is 13 meters. For reference, we also plot the curve related to the upper bound achieved with no multi-user interference. The proposed OOB-aided coordinated algorithm outperforms the uncoordinated one, which neglects co-beam interference.

![Graph showing sum-rate vs SNR](image)

Fig. 3: Sum-rate vs SNR. The average inter-UE distance is 13 m. The OOB-aided coordinated algorithm outperforms the uncoordinated one. The coordination gain increases with the SNR.

In Fig. 4, we show the sum-rate of the proposed algorithms as a function of the average inter-UE distance, for a mmWave SNR of 1 dB. The coordination among the UEs allows for huge SE gains for inter-UE distances below 15 meters. As the average inter-UE distance increases – and so, there is less chance for the co-beam interference to occur – the performance gap between the two algorithms narrows.
Fig. 4: Sum-rate vs average inter-UE distance. The SNR is fixed to 1 dB. The performance gain achieved through coordination decreases with the inter-UE distance.

V. CONCLUSIONS

In mmWave communications, suitable strategies for interference minimization can be applied in the beam domain through e.g. exploiting spatial side-information. In this work, we introduced a low-overhead OOB-aided decentralized beam selection algorithm for a mmWave uplink multi-user scenario, leading to improved interference management. The core of the proposed algorithm resides in the D2D-enabled hierarchical information exchange, which allows for a low-overhead approach to the beam selection problem. Finding clear relationships between mmWave and lower bands radio environments is essential for OOB-aided approaches – in particular, towards robust algorithms taking channels discrepancies into account – and it is an interesting open research problem.
