Summary
Rupture of aortic sinus aneurysms is a rare cardiac malformation that is commonly observed in the right coronary sinus but is rarely observed in the noncoronary sinus. Here, we report a case of aneurysm of the aortic sinus that ruptured into the left ventricular outflow tract and was diagnosed with left ventricular opacification. Left heart echocardiography can clearly demonstrate the structure of the heart and is one of the important diagnostic methods for diagnosing ruptured aortic sinus aneurysms. This observes the perfusion sequence of blood flow to clearly reveal the source, direction, and location of the ruptured aortic sinus aneurysm.

(Key words: Echocardiography, Ruptured aneurysm, Myocardial contrast echocardiography)

Case Report
A 47-year-old male visited the hospital with chief complaints of shortness of breath following exercise for the past two months. The patient has a past history of third-degree atrioventricular (AV) block. On examination, his heart rate and blood pressure were 64/minute and 159/77 mmHg, respectively. On percussion, heart sounds were detected toward the left side of the chest, and the leftmost point of the heart sound was located 0.5 cm inside the midline of the left intercostal bone in the fifth intercostal space. On auscultation, a 3/6-stage systolic jet-like murmur and a diastolic water-like murmur could be heard in the aortic valve area. Cardiac ultrasonography using a GE Vivid E9 system revealed an NCS, which measured 61 × 33 mm and extended to the anterior mitral valve (Figure 1A and C). An echo near the left ventricular outflow tract was interrupted, and a 4.5 mm wide break was observed at the top. During the diastolic phase, the blood flow into the left ventricular outflow tract was visible. Furthermore, the mouth of the aortic valve was squeezed, flow velocity increased, and valve regurgitations were detected (Figure 1B and D). Doppler ultrasound revealed a maximum flow rate of 229 cm/s at the aortic valve, with a pressure gradient of 20 mmHg. Color Doppler flow imaging (CDFI) demonstrated severe aortic regurgitation (AR). The mitral valve could open well but could not completely close. CDFI also demonstrated severe mitral regurgitation (MR). The conclusions for the ultrasound were as follows: (1) possible interlining hematoma between the NCS and mi-
Figure 1.  A: Long-axis view of the left ventricle revealing that the aorta has no posterior sinus bulge, forming a cystic structure, that is, NCS.  B: Left ventricular long-axis section (CDFI) revealing AR (white arrow) and an unsupervised sinus tumor that broke into the left ventricular outflow tract (yellow arrow).  C: Nonstandard five-chamber view. The NCS was bulging into the anterior mitral side.  D: Five-chamber view of the heart (CDFI): AR (yellow arrow).  E: Transesophageal echocardiography. The short axis of the aorta revealed that the NCS was bulging outward, forming a tumor-like structure (NCS).  F: Transesophageal echocardiography. The left ventricular long-axis view reveals the NCS tumor rupture in the left ventricular outflow tract (P).  G: LVO. The left ventricular long-axis view reveals that the angiography agent entered the NCS through the ascending aorta (the ascending aorta and NCS traffic port between the two white lines).  H: LVO. The left ventricular long-axis section reveals the contrast agent entering the left ventricular outflow tract via the NCS (the NCS is in the left ventricular outflow tract between the two white lines), and the NCS cyst wall thrombus formation (white arrow) is visible. RV indicates right ventricle; LV, left ventricle; LA, left atrium; AO, aortic ostium; NCS, noncoronary sinus; P, noncoronary sinus tumor breach in the left ventricular outflow tract; L, left coronary sinus; R, right coronary sinus; and N, noncoronary sinus.

Discussion
Aortic sinus tumors are mostly caused by congenital factors that interrupt or soften the muscles and elastic fibers of the aortic sinus wall. The middle layer of the aortic sinus is separated from the annulus. Under hemody-
namics, the sinus wall gradually becomes thinner and bulges outward to form a cystic substance.\(^5\)\(^6\) In addition, acquired factors such as infective endocarditis, syphilis, arteriosclerosis, and Marfan syndrome can also lead to aortic sinus aneurysms.\(^7\) For the present patient, the investigators considered that the ascending aortic wall with multifocal mucoid degeneration and hypertension both contributed to the formation of the aortic sinus aneurysm and rupture. Aortic sinus aneurysms are most commonly observed in the right coronary sinus, less frequently observed in the NCS, and rarely observed in the left coronary sinus. The broken part is more common in the right ventricle, followed by the right atrium, but rarely in the left atrium and left ventricle, which is classified as type V.\(^8\)\(^9\) The pressure inside the capsule gradually increases, the wall of the sac becomes thinner and thinned, and finally the sinus aneurysm ruptures into one of the cardiac chambers. When the aneurysm is large, it could compress the surrounding conducting system, such as the AV node or the His bundle, resulting in arrhythmia and conduction block. The aneurysm protrudes into the right ventricular outflow tract, tricuspid valve, and coronary ostium, which causes local obstruction. After the rupture of the sinus aneurysm, the cardiac chamber load is sharply increased, which may lead to the dilatation of the heart chamber and cardiac insufficiency. Furthermore, this could enter into the pericardium, causing tamponade and even death. Owing to the serious clinical consequences of a ruptured aortic sinus aneurysm, surgery should be immediately performed after the diagnosis.

In the present case, the NCS aneurysm ruptured into the left ventricular outflow tract and caused an aortic and mitral valve injury, which is an extremely rare consequence of a ruptured aneurysm. The patient initially underwent conventional echocardiography, which revealed a protruding NCS forming a sac-like structure. This sac involved both the left ventricular outflow tract and the left atrium. However, because of the AR and MR, conventional ultrasound could not clearly demonstrate the NCS aneurysm and position of the rupture. Furthermore, it could not rule out the possibility of an interlining hematoma between the NCS and the anterior lobe of the mitral valve. Left heart echocardiography revealed that the contrast entered the capsular bag immediately after entering the ascending aorta through the left ventricle, and it entered the left ventricular outflow tract through the rupture. Filling defects could be observed in the sac. Hence, it could be concluded that the sac is an aortic sinus aneurysm that broke into the left ventricular outflow tract. Thrombosis presented in the sinus aneurysm, which was consistent with the intraoperative observation. However, MCE examination revealed no significant dysfunction in the coronary microcirculation. In the present case, the contrast did not enter the anterior mitral valve. Hence, the diagnosis of an interlining hematoma was excluded. In addition, the contrast agent could be used to find the echo enhancement and thickening of the anterior and posterior wall of the ascending aorta. Coronary CTA confirmed the above diagnosis and ruled out coronary lesions. Left heart echocardiography played a major role in the diagnosis of the present case. LVO examination could demonstrate the source and path of the aneurysm and determine the rupture location of the sinus. It also could detect the thrombus, which was missed by conventional echocardiography. Furthermore, LVO can improve the image quality of the patients and identify the changes in the anterior and posterior walls of the ascending aorta.\(^10\)\(^11\) MCE can evaluate coronary microcirculation perfusion and accurately determine disturbances in the coronary microcirculation by assessing the myocardial blood flow.\(^12\)\(^13\) Left heart echocardiography is important for complicated aortic sinus aneurysms and can reveal the origin of the sinus, its relationship with the surrounding structures, the path of the sinus tumor, and the location of the rupture. Furthermore, it can evaluate the microcirculation function of the coronary artery, in order to provide accurate information for the surgery.\(^14\)

Aortic sinus aneurysms differ in location and rupture into the heart chamber. Ultrasound manifestations are diverse and can, thereby, be easily missed and misdiagnosed. Hence, these types of aneurysms need to be differentiated from various types of cardiac malformations.\(^15\) First, for ventricular septal defects, the rupture of a right aneurysm is usually complicated by ventricular septal defects. In the present case, there was an NCS lesion. Thus, this was easy to differentiate from a ventricular septal defect. Second, for valsalva sinus pseudoaneurysms, these are caused by trauma, but there was no relationship between the pseudoaneurysm and the heart chamber. In the present case, there was no history of trauma. Left heart echocardiography identified a port of communication between the cystic structure and the left ventricular outflow tract. Hence, the diagnosis of valsalva sinus pseudoaneurysm was ruled out. Third, no ruptured coronary sinus in the mitral valve occurred to form a dissection hematoma. Left heart echocardiography revealed that the contrast did not enter the mitral valve, and the mitral valve tissue was separated by dissection. Hence, the diagnosis of dissection of mitral rupture into the mitral valve was ruled out. Finally, Marfan syndrome was considered, which could result in an aortic sinus aneurysm along the lining of the aorta. However, the absence of lesions in the bones and eyes of the patient negated the occurrence of rupture of the aortic sinus tumor caused by Marfan syndrome.

Therefore, two-dimensional echocardiography, CDFI, and spectral Doppler technology can be used to noninvasively and accurately diagnose aortic sinus tumors and determine the location, size, and blood flow of aortic sinus aneurysms. Left heart echocardiography may clearly reveal the structure of the heart, thereby further clarifying the relationship between the aneurysm and the surrounding tissues. Furthermore, it offers the possibility of observing sinus aneurysm breaches, thereby offering a unique diagnostic advantage for patients with difficult-to-diagnose aneurysms, such as complex aneurysms.
