Abstract. The surface electric characteristics of bare strange stars are investigated with the inclusion of boundary effects. The thickness of the electron layer where pairs can be spontaneously created is calculated as a function of the bag parameters. We find that previous estimates are representative for bag parameters within a rather wide range, and therefore our results favor the thermal radiation mechanism of bare strange stars advanced by V. V. Usov.

Key words: Radiation mechanisms: thermal — Elementary particles — Stars: neutron

1. Introduction

It is of great importance to identify strange stars; a new window of distinguishing neutron stars and bare strange stars (BSSs) has been proposed recently according to their sharp differences of surface conditions (Xu, Zhang, Qiao 2001; Usov 2001a). It is therefore essential to study the surface properties of BSSs in details, e.g., the degree of the thermal luminosity of a hot BSS.

The surface electric field should be very strong (\(\sim 10^{17}\) V/cm) near the bare quark surface of a strange star because of the mass difference of the strange quark and the up (or down) quark (Alcock et al. 1986), which could play an important role in producing the thermal emission of BSSs by the Usov mechanism (Usov 1998, Usov 2001b), an important role in producing the thermal emission of strange stars (BSSs) has been proposed recently according to their sharp differences of surface conditions (Xu, Zhang, Qiao 2001; Usov 2001a). It is therefore essential to study the surface properties of BSSs in details, e.g., the degree of the thermal luminosity of a hot BSS.

The surface electric field should be very strong (\(\sim 10^{17}\) V/cm) near the bare quark surface of a strange star because of the mass difference of the strange quark and the up (or down) quark (Alcock et al. 1986), which could play an important role in producing the thermal emission of BSSs by the Usov mechanism (Usov 1998, Usov 2001b), because the strange quark matter is a poor radiator of thermal photons at frequencies less than its plasma frequency (\(\sim 20\) MeV) (Alcock et al. 1986). The basic idea of the Usov mechanism is that \(e^+e^-\) pairs are created rapidly in a few empty quantum states with energy \(\epsilon < \epsilon_F - 2mc^2\) (\(\epsilon_F\) is the Fermi energy, \(m\) the electron mass) due to the very strong electric field in an electron layer (with a height of \(\sim 500\) fm above quark surface); the pairs subsequently annihilate into photons which are then thermalized in the electron layer around a BSS. This radiative mechanism has been applied tentatively to soft \(\gamma\) ray repeaters (Usov 2001c; Usov 2001d) recently. In addition, the strong electric field plays an essential role in forming a possible crust around a strange star, which has been investigated extensively by many authors (e.g., Martemyanov 1992; Kettner et al. 1995; Huang & Lu 1997; Phukon 2000; see Zdunik, Haensel & Gourgoulhon 2001 for the recent development with the inclusion of rotating and general-relativistic effects). Also it should be noted that this electric field has some important implications on pulsar radio emission mechanisms (Xu & Qiao 1998; Xu, Qiao, Zhang 1999; Xu, Zhang, Qiao 2001).

In fact the Usov mechanism of pair production depends on many parameters; it is therefore imperative to study the dependence of the process on these parameters. With some typical parameters chosen by Usov in his calculations, the resultant thickness of the electron layer with electric field \(E \gtrsim 1.3 \times 10^{16}\) V/cm (the critical field necessary for pair production), \(\Delta r_E\), is \(\sim 500\) fm. However the proper determination of the thickness \(\Delta r_E\) should be done with the dynamical theory of the strange quark matter. Because of the untractable nature of the quantum chromodynamics, some phenomenological models, i.e., the MIT bag model (e.g., Jensen & Madsen 1996), the quark mass-density-dependent model (e.g., Lugones & Benvenuto 1995), and the quark potential model (e.g., Dey et al. 1998), have been applied to the descriptions of the strange quark matter. In the bag model, \(\Delta r_E\) is a function of \(\alpha_c\) (the coupling constant for strong interactions), \(m_s\) (the strange quark mass), and \(B\) (the bag constant). Also it should be noticed that the quark number densities, \(n_i\) (\(i = u, d, s\) for up, down and strange quarks, respectively), are assumed to be uniform below the quark surface, and therefore the quark charge density (\(2n_u - n_d - n_s\))/3 = \(V_q^3/(3\pi^2)\) is constant near the surface. The potential \(V_q\) is usually chosen as 20 MeV for typical cases. However the quark number densities should not be uniform near the surface if boundary effects are included, since charge neutrality is broken there.

In this paper we improve the calculation of the electric field in the vicinity of a BSS surface, using the popular bag model and the Thomas-Fermi model. We investigate the
2. Calculation of the electric field near the quark surface

The interesting electric properties of strange stars were first noted by Alcock, Farhi & Olinto (1986), who presented numerical calculations of the electric potentials of strange stars with or without crusts. Analytical solutions of the electron number density and electric field were also formulated, which could be helpful in dealing with some physical processes near the quark surfaces of strange stars (Xu & Qiao 1999). In this section, the bag model is applied to calculate the quark charge density; the Thomas-Fermi Model is employed to find $\Delta E$ dependence on $\alpha_c$, $m_s$, and $B$, with the inclusion of boundary effects.

2.1. Equations

In our calculation, the quarks and electrons near the surface of the strange star keep chemical equilibrium locally; the relation between charge density and electric potential is described by the classical Poisson equation. The thermodynamic potentials $\Omega_i$ as functions of chemical potentials $\mu_i$ (i = u, d, s, e), $m_s$ and $\alpha_c$ can be found in literature (Alcock et al. 1986). In the chemical equilibrium of weak interaction,

$$\mu_d = \mu_s = \mu, \quad \mu_e + \mu_u = \mu,$$

$$\frac{d^2V}{dz^2} = n_e + \frac{1}{3} n_d + \frac{1}{3} n_s - \frac{2}{3} n_u,$$

$$n_i = -\frac{\partial \Omega_i}{\partial \mu_i},$$

where $z$ is a measured height above the quark surface.

The quark number densities drop to zero on the surface, but they are not uniform below the surface if the boundary effects are considered. The chemical potential $\mu$ can be determined by the condition that the pressure on the quark surface is zero, $P|_{z=0} = 0$. The pressure is

$$P = -\sum_i \Omega_i - B \ (\text{Alcock et al. 1986}).$$

The kinetic energy of electrons is equal to the electric potential, $p_e = V$, in the Thomas-Fermi model. The electron number density reads (Alcock et al. 1986)

$$n_e = \frac{p_e^3}{3\pi^2} = \frac{V^3}{3\pi^2}.$$  

Note that the thermodynamical potential $\Omega_i$ is defined when the electric potential $V$ is assumed as zero. We thus replace $\mu_i$ with $\mu_i - qV$ in Eq. [6], where $q$ is the particle charge. Finally we come to,

$$\frac{d^2V}{dz^2} = \left\{ \begin{array}{ll}
\frac{V^3}{3\pi^2} + \frac{1}{3} n_s(V) + \frac{1}{3} \left( 1 + \frac{1}{3} \right) \left( \mu + \frac{1}{3} V \right)^3 & \text{if } z < 0 \\
\frac{2}{3} \left( \mu - \frac{2}{3} V \right)^3 & \text{if } z \geq 0
\end{array} \right.$$  

where the complex term $n_s(V)$ can be derived from chemical potentials $\Omega_i$.

The boundary conditions for Eq.[5] are

$$z \to -\infty: \quad V \to V_0, \quad \text{d}V/\text{d}z \to 0;$$

$$z \to +\infty: \quad V \to 0, \quad \text{d}V/\text{d}z \to 0.$$  

where $V_0$ is the electric potential in the deep core of the strange star, which is determined from Eq.(6) by letting the left hand side equal zero.

2.2. Results

By integrating Eq.[5] in $(-\infty, V_c)$ and $(V_c, +\infty)$ respectively, with the boundary conditions, we get the expression of the electric field $E = -\text{d}V/\text{d}z$, where $V_c = V|_{z=0}$. Obviously $V_c$ is a function of $\alpha_c$, which can be obtained from the continuity of $E$ at $z = 0$. Substituting $V_c$ into the equations of $E$ and then integrating them, we get the expression of $V$. For $z \geq 0$, we find

$$V(z) = \frac{V_c}{1 + \frac{V_c}{\sqrt{6\pi}}},$$

$$E(z) = \frac{\text{d}V}{\text{d}z} = \frac{1}{\sqrt{6\pi}} \frac{V_c^2}{1 + \frac{V_c}{\sqrt{6\pi}}}.$$

Several numerical results are obtained, which are shown in Table 1 and Figs.1-4. First, we study the electric characteristics of a BSS for different values of $\alpha_c$, assuming $\mu = 300$ MeV, $m_s = 200$ MeV, and the renormalization point $\rho_B = 313$ MeV. The quark and electron number densities $\{n_i\}$ when $z \to -\infty$, as well as potentials of $V_0$ and $V_c$, are listed in Table 1 for $\alpha_c = 0.1, 0.3, 0.5, 0.7, 0.9$, respectively. The electric potential $V$ and field $E$ are also plotted in Figs.1-3 for this case. We see from Fig.1 that the potential curve becomes flatter.

2 Generally there is a relation between $\mu$ and $B$, $\mu = \mu(B)$. In this assumption $B^{1/4} \sim 145$ MeV.

| $\alpha_c$ | 0   | 0.1 | 0.3 | 0.5 | 0.7 | 0.9 |
|------------|-----|-----|-----|-----|-----|-----|
| $B^{1/4}/\text{MeV}$ | 146 | 144 | 139 | 133 | 127 | 120 |
| $n_u/10^{44}$ m$^{-3}$ | 2.86 | 2.71 | 2.41 | 2.10 | 1.80 | 1.48 |
| $n_d/10^{44}$ m$^{-3}$ | 3.95 | 3.68 | 3.14 | 2.60 | 2.07 | 1.54 |
| $n_s/10^{44}$ m$^{-3}$ | 1.77 | 1.74 | 1.68 | 1.61 | 1.52 | 1.42 |
| $V_0/\text{MeV}$ | 31.65 | 29.99 | 26.05 | 20.93 | 14.01 | 4.08 |
| $V_c/\text{MeV}$ | 30.69 | 29.11 | 25.34 | 20.44 | 13.77 | 4.06 |

Table 1. The particle number densities far below the quark surface, and the potentials of $V_0 = V(z = -\infty)$ and $V_c = V(z = 0)$, for different values of $\alpha_c$.

when the coupling constant $\alpha_c$ increases. Also it should be noted from Figs.2 and 3 that the electric filed $E$ changes rather slowly for $z > 0$, but varies rapidly for $z < 0$. This indicates the non-symmetric nature of the electric field with respect to the quark surface of $z = 0$.

Secondly, we investigate numerically the thickness, $\Delta r_E$, of the electron layer where pairs can be created, as functions of the bag parameters $m_s$, $B$, and $\alpha_c$. The results are shown in Fig.4. It is found that the Usov mechanism can work for bag parameters within a rather wide range. The thickness $\Delta r_E$ could be large enough (i.e., $\Delta r_E \gtrsim 500$ fm) as long as (1) $B$ is not too large and $m_s$ is not too small, or (2) $B$ is not too small and $m_s$ is not too large. Increasing of $\alpha_c$ has an adverse influence on the Usov mechanism. For instance in Fig.2, the field $E$ can not exceed the critical field $E_c = 1.3 \times 10^{16}$ V/cm (necessary for pair production) if $\alpha_c > 0.94$. Nevertheless previous dynamical
3. Conclusion & Discussion

We have improved the calculation of the electric characteristics of bare strange stars with the inclusion of boundary effects (i.e., the effects of non-local neutrality near and below the quark surface). From our calculation, we find that the Usov mechanism can work for bag parameters within a rather wide range.

As shown in Table 1, both \( V_c \) and \( V_0 \), as well as their very small difference, decrease as \( \alpha_c \) increases. Our results on the electric potential \( V(z) \) for \( z < 0 \) is quit different from the previous calculation given by Alcock et al. (1986) where the boundary effects were not included (see Fig. 1). It is shown that the strong electric field resides only about \( \sim 10 \) fm below the quark surface (see Fig. 3), rather than \( \sim 10^2 \) fm obtained by Alcock et al. (1986).

We can proof that \( E \) is almost an exponential function of \( z \) below the quark surface. Denote the right hand side of the Eq.(8) as \( f(V) \). As \( z \to -\infty \), namely \( V \to V_0 \), we have \( f(V) \to 0 \). Approximating \( f(V) \) as \( f'(V_0) (V - V_0) \), we can obtain \( E = -\sqrt{f'(V_0)} \exp[\sqrt{f'(V_0)}z] \) and \( V = V_0 - \exp[\sqrt{f'(V_0)}z] \) for \( z < 0 \).
