**KEY WORDS**

Bile acid; Sphingosine-1 phosphate receptor; Hepatic lipid metabolism

**Abstract** The liver is the central organ involved in lipid metabolism. Dyslipidemia and its related disorders, including non-alcoholic fatty liver disease (NAFLD), obesity and other metabolic diseases, are of increasing public health concern due to their increasing prevalence in the population. Besides their well-characterized functions in cholesterol homeostasis and nutrient absorption, bile acids are also important metabolic regulators and function as signaling hormones by activating specific nuclear receptors, G-protein coupled receptors, and multiple signaling pathways. Recent studies identified a new signaling pathway by which conjugated bile acids (CBA) activate the extracellular regulated protein kinases (ERK1/2) and protein kinase B (AKT) signaling pathway via sphingosine-1-phosphate receptor 2 (S1PR2). CBA-induced activation of S1PR2 is a key regulator of sphingosine kinase 2 (SphK2) and...
1. Introduction

Bile acids are synthesized from cholesterol and are known to solubilize cholesterol in the gallbladder and promote the digestion and absorption of dietary fats and fat-soluble vitamins (A, D, E and K) in the intestines. The production of bile acids is also known to be one of the predominant mechanisms for excretion of excess cholesterol from the body. In addition to their beneficial effects, bile acids also produce toxic effects in the liver. It is becoming increasingly evident that bile acids exert various biological effects by activating different signaling pathways. However, the concept of bile acids acting as signaling molecules is recent. It was not until the past two decades that studies have reported that bile acids act as natural ligands for the farnesoid X receptor (FXR). Following this discovery, bile acids have been shown to activate other nuclear receptors (pregnane X receptor, vitamin D receptor), G protein coupled receptors (GPCRs) (G-protein-coupled bile acid receptor 5 (TGR5), masurcan receptor 2 (M2), sphingosine-1-phosphate receptor 2 (S1PR2)) and cellular signaling pathways (c-Jun N-terminal kinase (JNK1/2), protein kinase B (AKT), and extracellular regulated protein kinases (ERK1/2)).

Bile acids have also been implicated in the inflammatory response and various liver diseases, as well as the promotion of cancers such as colon cancer and cholangiocarcinoma. The emerging role of bile acids as hormones and nutrient signaling molecules helped contribute to our understanding of glucose and lipid metabolism. In this review, we will discuss our current understanding of how bile acids and the S1PR2 regulate hepatic lipid metabolism.

2. Enterohepatic circulation of bile acids

Bile acids are synthesized from cholesterol in the hepatocytes and are actively transported into the bile duct system using ATP-binding cassette (ABC) transporter after conjugation with glycine or taurine. Hepatocytes secrete bile acids via bile salt export proteins (BSEP, ABCB11) along with phosphatidylcholine by ABCB4 and cholesterol by ABCG5/ABCG8. As detergent molecules, bile acids keep cholesterol in solution within the gallbladder by forming micelles with cholesterol and phospholipids. The ratio of conjugated bile acids, cholesterol and phospholipids is highly regulated and excess cholesterol has been linked to an increased risk for cholesterol gallstone formation. Bile is stored in the gallbladder and excreted into the duodenum in response to eating to activate pancreatic lipases and solubilize lipids to promote dietary fat absorption. Approximately 95% of bile acids are reabsorbed through the ileum by ileal sodium-dependent bile acid transporter (IBAT, SLC10A2). Bile acids reabsorbed from the intestines travel through the portal blood and return to the liver via the sodium taurocholate cotransporting polypeptide (NTCP, SLC10A1). A small portion of primary bile acids are converted into secondary bile acids by anaerobic gut bacteria, which can be either passively absorbed from the large intestine or secreted in the feces. During enterohepatic circulation, bile acids lost through fecal excretion must be replenished by de novo bile acid synthesis.

3. Bile acid synthesis

Bile acids are direct end-products of cholesterol catabolism. In humans, two primary bile acids, CA (3α, 7α, 12α-trihydroxycholanoic acid or cholic acid) and CDCA (3α, 7α-dihydroxycholanoic acid or chenodeoxycholic acid), are formed in the liver through two synthetic pathways, the neutral pathway and the acidic pathway (Fig. 1). The neutral pathway, also called the classic pathway, is the major pathway of generating bile acids for humans under physiological conditions and produces both CA and CDCA. The initiation of bile acid synthesis involves the enzyme cholesterol 7α-hydroxylase (CYP7A1) to catalyze the 7α-hydroxylation of cholesterol. In this rate-limiting step, CYP7A1 gene expression is tightly regulated at the transcriptional level and by a negative feedback mechanism involving bile acids, glucagon, tumor necrosis factor α (TNFα) and fibroblast growth factor 15/19 (FGF15/19). In ileocytes, bile acids stimulate the production of FGF15/19 which can bind to the fibroblast growth factor receptor 4 (FGFR4)/β-Klotho complex on the cell membrane of hepatocytes and regulate bile acids and carbohydrate metabolism via activating several signaling cascades including JNK1/2 and ERK1/2. Activation of the JNK1/2 pathway has been shown to repress Cyp7a1 gene expression in hepatocytes, Fgfr4 and β-Klotho null mice have been shown to contain increased Cyp7a1 mRNA levels and bile acid levels. These results demonstrate the critical role FGF15/19, an FXR target gene, plays in the regulation of CYP7A1 and bile acid synthesis. In addition, FXR can induce the expression of an atypical orphan nuclear receptor, small heterodimer partner (SHP). SHP has no DNA-binding domain and functions as a common transcriptional repressor of nuclear receptors. SHP can form a heterodimer with several transcription factors, including hepatocyte nuclear factor 4α (HNF-4α) and liver-related homolog-1 (LRH-1), to inhibit their transactivation activities, which results in inhibiting Cyp7a1 and sterol 12α-hydroxylase (Cyp8b1) transcription.

The acidic pathway is initiated by sterol 27-hydroxylase (CYP27A1) in the mitochondrial inner membrane and has been shown to be more active in cirrhosis and various liver diseases. Since cholesterol concentration is very low in the inner mitochondrial membrane, the rate limiting step in acidic pathway may be the transport of cholesterol into the mitochondrion. The acidic pathway generates mostly CDCA. In addition to the liver, CYP27A1 is ubiquitously expressed in most tissues including the macrophages. CYP27A1 can catalyze cholesterol to form oxysterols by introducing a hydroxyl group to the carbon at either the 27 or 25 position in cholesterol. The products, 27-hydroxycholesterol and 25-hydroxycholesterol, are known to be regulatory oxysterols that are important in maintaining cholesterol and fat levels in the liver.
phospholipid and cannot easily pass the membrane lipid bilayer without transporters. ABC transporters, including ABCA1 and ABCC1, have been identified as active transporters of S1P\(^{27,29}\). In addition, spinster homologue 2 (Sphns2), a member of the major facilitator superfamily, has been shown to mediate S1P secretion\(^{30,31}\). Extracellular S1P exerts its function via activating five different G protein coupled receptors (S1PR1–5) on the cell membrane to induce various cellular responses\(^{32–34}\) (Fig. 2). In the nucleus, pERK1/2 phosphorylates and activates SphK2 to synthesize S1P. Nuclear S1P has been identified as a potent histone deacetylase 1 and 2 inhibitor\(^{35}\).

S1PRs are differentially expressed in various tissues, and the individual S1PR expression level varies under different physiological and pathological conditions\(^{36}\). Each S1PR is coupled to specific G proteins, which mediate unique functions. S1PR1 is ubiquitously expressed and plays a key role in angiogenesis, vascular maturation and immune cell trafficking\(^{36,37}\). Deletion of S1PR1 affects maturation and is embryonically lethal\(^{38}\). S1PR1 has been reported only to be linked with Gαi\(^{37}\). S1PR2 is highly expressed in vascular smooth muscle cells, heart, liver, kidney, spleen, lung and brain\(^{39,41}\). Unlike S1PR1, mice deficient in S1PR2 exhibit no phenotypic defects, but develop spontaneous and sporadic seizures\(^{42}\). S1PR2/–/ mouse studies have also shown S1PR2 to be responsible for proper development of the auditory and vestibular systems\(^{43}\). In addition, S1PR2 is coupled to different G proteins. Each of these G proteins activates different pathways involved in various biological processes. S1PR2 has been reported to be required for mast cell degranulation and chemotaxis towards the site of inflammation\(^{44}\). S1PR3 is highly expressed in the brain, heart, lung, spleen, kidney, liver, intestine and skeletal muscle\(^{45}\). Similar to S1PR2, S1PR3 is also coupled to different G proteins. S1PR3 plays an important role in pulmonary epithelial and endothelial barriers\(^{46}\). S1PR4 is primarily expressed in leukocytes and has been suggested to be a regulator of T cell cytokine production\(^{37}\). S1PR5 expression is largely localized in the white matter of the central nervous system with oligodendrocytes having the highest expression. S1pr5 knockout mice did not exhibit any changes in myelination\(^{48}\). The functional role of S1PR5 is unclear. However, recent studies have suggested a role in natural killer cells (NK) mobilization in the immune system\(^{49,50}\).

### 5. Bile acids, S1PR2 and lipid metabolism

The role of bile acids regulating lipid metabolism in humans has been well established. Cholesterol gallstone patients treated with CDCA experience a decrease in hepatic very-low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients with hypercholesterolemia received bile acid binding resins, which increased serum levels of VLDL-triglycerides and high density lipoprotein (HDL)-cholesterol while reducing low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients CDCA experience a decrease in hepatic very-low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients with hypercholesterolemia received bile acid binding resins, which increased serum levels of VLDL-triglycerides and high density lipoprotein (HDL)-cholesterol while reducing low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients CDCA experience a decrease in hepatic very-low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients with hypercholesterolemia received bile acid binding resins, which increased serum levels of VLDL-triglycerides and high density lipoprotein (HDL)-cholesterol while reducing low-density lipoprotein (VLDL) production and plasma triglyceride levels. Patients CDCA experience.

---

**Figure 1** Bile acid synthesis and metabolism. Two major pathways are involved in bile acid synthesis. The neutral (or classic) pathway is controlled by CYP7A1 in the endoplasmic reticulum. The acidic (or alternative) pathway is initiated by sterol CYP27A1 in mitochondria. CYP8B1 is required to synthesize CA. Oxysterol 7α-hydroxylase (CYP7B1) is involved in the formation of CDCA in the acidic pathway. The neutral pathway is also able to form CDCA by CYP27A1. Primary bile acids are metabolized by gut bacteria to form the secondary bile acids, DCA and LCA.

The primary bile acids CA and CDCA are converted into deoxycholic acid (DCA) and lithocholic acid (LCA) respectively by a small population of intestinal anaerobic bacteria.

### 4. Sphingosine-1-phosphate and sphingosine-1-phosphate receptors

Sphingosine-1-phosphate (S1P) is a simple, but potent bioactive sphingolipid. It is involved in a variety of cellular processes, including cell proliferation, differentiation, motility, angiogenesis, inflammation and malignant transformation\(^{77}\). S1P is synthesized by sphingosine kinase 1 (SphK1) or sphingosine kinase 2 (SphK2), which transfer the phosphate from ATP to the 1-hydroxyl group of sphingosine. SphK1 and SphK2 reside in different subcellular compartments and regulate the production of S1P. SphK1 is located in the cytoplasm, and upon an external signal, it translocates to the plasma membrane to convert sphingosine to S1P. Intracellular S1P can act as a signaling molecule, but its target has not been well-characterized. S1P can be converted to sphingosine by cytosolic S1P phosphatases or degraded by S1P lyase (SPL) to ethanolamine phosphate and hexadecanal. In order to activate the cell surface GPCRs, S1P must be transported to the cell’s exterior, but S1P is a small polar
mice exhibit decreased plasma cholesterol and triglycerides upon treatment with bile acids or FXR agonists. The FXR inducible gene, FGF19, has been shown to repress lipogenesis and increase metabolism. Fgf19 transgenic mice exhibited resistance to diet-induced obesity and insulin resistance. Interestingly, overexpressing Cyp7a1 in mice prevents fat-induced obesity and insulin resistance.

S1PR2 is highly expressed in the liver and plays a unique and critical role in the pathophysiology of the liver. The role of S1PR2 in bile acid-mediated hepatic lipid metabolism was identified in recent studies. In primary rodent hepatocytes, conjugated bile acids activate S1PR2, which further activates the downstream ERK1/2 and AKT signaling pathways. Bile acid-mediated activation of ERK1/2 and AKT signaling pathway plays an important role in the regulation of hepatic glucose and lipid metabolism. In primary rat hepatocytes, insulin and bile acids both activated glycogen synthase activity to a similar extent. Infusion of taurocholate (TCA) into the chronic bile fistula rat rapidly activated the AKT and ERK1/2 signaling pathway and glycogen synthase activity. In addition, TCA induced a rapid down-regulation of the gluconeogenic genes, PEP carboxykinase (Pepck) and glucose-6-phosphatase (G-6Pase) and a marked up-regulation of Shp mRNA in the livers. These results suggest that TCA has insulin-like activity to regulate hepatic glucose metabolism both in vitro and in vivo.

A recent study reported S1pr2 null mice rapidly develop overt fatty livers on a high fat diet compared to wild-type mice, suggesting that S1PR2 is an important regulator of hepatic lipid metabolism. Infusion of taurocholate into the chronic bile fistula rat or overexpression of the gene encoding S1PR2 in mouse hepatocytes significantly up-regulated hepatic SphK2, but not SphK1. Interestingly, key genes encoding nuclear receptors/enzymes involved in nutrient metabolism were significantly down-regulated in livers of S1pr2−/− and Sphk2−/− mice. In contrast, overexpression of the gene encoding S1PR2 in primary mouse hepatocytes increased mRNA levels of key genes involved in nutrient metabolism. Previous studies have identified nuclear S1P as an endogenous inhibitor of HDAC1/2. In the primary hepatocytes of S1pr2−/− and Sphk2−/− mice, nuclear S1P levels and the acetylation of H3K9, H4K5 and H2BK12 were significantly decreased. Both S1pr2−/− and Sphk2−/− mice rapidly developed fatty livers on a high fat diet suggesting the importance of conjugated bile acids, S1PR2 and SphK2 in regulating hepatic lipid metabolism. Our previous studies in rodent hepatocytes and human hepatocytes also reported that bile acid-induced ERK1/2 activation can be blocked not only by pertussis toxin (PTX), but also by the epidermal growth factor receptor (EGFR; ErbB-1) antagonist (AG1478) and the proto-oncogene tyrosine-protein kinase (SRC) inhibitor PP270. As illustrated in Fig. 3, inhibition of S1PR2 activation either by chemical antagonist (JTE-013) or PTX will block ERK1/2 activation in hepatocytes, suggesting that S1PR2-mediated signaling is the upstream of EGFR-mediated signaling.

Inflammation is believed to be an important factor in the development of type 2 diabetes and fatty liver disease. A Western diet is correlated with low grade chronic inflammation and insulin resistance. Inhibition of the insulin signaling pathway may decrease the ability of bile acids to activate FXRα and induce SHP and other FXR target genes, leading to an increased risk of fatty liver and non-alcoholic fatty liver disease (NAFLD). It has been reported that S1P inhibits macrophage migration to the inflammation site via S1PR2 activation. Hepatocyte proliferation and matrix remodeling occur during liver injury, and S1PR2 has been suggested to play a role in promoting the wound healing response.

6. Conclusions and future directions

Bile acids mediate complex biological activities. Current data supports the extensive interplay between bile acid-mediated signaling and insulin signaling in the regulation of lipid and nutrient metabolism in the liver. Bile acids not only activate nuclear receptors, but also activate GPCRs. The emerging roles of bile acids and S1PR2 in hepatic lipid metabolism have paved the way for the future direction of bile acid signaling research.
Currently, it is unclear what physiological role of ERK1/2 activation by bile acids and S1PR2 has on hepatic lipid metabolism. Future studies aimed at elucidating the downstream target genes of ERK1/2 and the mechanisms by which these genes are activated are important. Since the identification of GPCR, a lot of drugs have been developed to treat various diseases. GPCRs are the most successful category of drug targets to date\(^7\). Understanding the molecular basis of bile acids and S1PR2 in signaling pathways may provide an avenue for drug targets and therapeutic discoveries in various hepatic lipid disorders.
