We apply Density Matrix Renormalization Group methods to study the phase diagram of the quantum ANNNI model in the region of low frustration where the ferromagnetic coupling is larger than the next-nearest-neighbor antiferromagnetic one. By Finite Size Scaling on lattices with up to 80 sites we locate precisely the transition line from the ferromagnetic phase to a paramagnetic phase without spatial modulation. We then measure and analyze the spin-spin correlation function in order to determine the disorder transition line where a modulation appears. We give strong numerical support to the conjecture that the Peschel-Emery one-dimensional line actually coincides with the disorder line. We also show that the critical exponent governing the vanishing of the modulation parameter at the disorder transition is $\beta_q = 1/2$.

PACS numbers: 75.10.Jm, 73.43.Nq, 05.10.Cc

The ANNNI model is an axial Ising model with competing next-nearest-neighbor antiferromagnetic coupling in one direction. It is a paradigm for the study of competition between magnetic ordering, frustration and thermal disordering effects. Its phase diagram displays a rich variety of phases. In the most realistic three-dimensional case, it describes several physical systems from magnetic materials like CeSb to binary alloys or dielectrics like NaNO$_2$\textsuperscript{1}. In the more academic one-dimensional case, it is exactly solvable and several general properties can be rigorously proved about its phase diagram\textsuperscript{2}.

The two-dimensional case is nontrivial and not solvable, but its phase structure is much simpler than the 3d case. The model is believed to display 5 phases\textsuperscript{3}: Ferromagnetic $\uparrow\uparrow\uparrow\uparrow\uparrow\uparrow$, antiphase $\uparrow\uparrow\downarrow\downarrow\downarrow\downarrow$, paramagnetic with or without modulation and floating phase with algebraically decaying spin correlations. This picture is supported by various analytical\textsuperscript{4} and numerical\textsuperscript{5} investigations based on a variety of approximations. However, lacking an exact solution, the precise location of the various transitions is not known beyond approximate treatments. Actually there is no rigorous proof of the existence of all the above phases. In particular the very existence of the floating phase has been recently under debate\textsuperscript{6}.

To further simplify the analysis, the 2d case can be studied in the Hamiltonian limit which is a one-dimensional quantum spin $S = 1/2$ chain with next-nearest-neighbor coupling. The chain interacts with an external field playing the role of the temperature and triggering phase transitions. The Hamiltonian limit, also called TAM model (Transverse ANNNI) is very interesting in itself being a simple example where several complicated quantum phase transitions do occur with drastic changes in the qualitative features of the ground state\textsuperscript{7}.

The accurate numerical study of the TAM model is challenging notwithstanding its relative simplicity. In this Letter we address an open conjecture concerning its disorder line by employing Density Matrix Renormalization Group methods.

To illustrate the problem, we introduce the TAM Hamiltonian with open boundary conditions which reads

$$H = -J_1 \sum_{i=1}^{L-1} \sigma_i^x \sigma_{i+1}^x - J_2 \sum_{i=1}^{L-2} \sigma_i^x \sigma_{i+2}^x - B \sum_{i=1}^{L} \sigma_i^z.$$  \hspace{1cm} (1)

We shall present our results in terms of the adimensional ratios $\kappa =-J_2/J_1$ and $B/J_1$ which are the only parameters that describe the properties of the ground state.

The qualitative phase diagram of the TAM model is quite different in the two regions $\kappa < 1/2$ or $\kappa > 1/2$. For $\kappa < 1/2$, the model is in a ferromagnetic phase at low magnetic field $B$. At $B_{c,1}$, a transition in the Ising class makes the ground state paramagnetic with exponentially decaying spin-spin correlation functions. Increasing further the external field we expect a new transition for $B > B_{c,2} > B_{c,1}$ where the model is still gapped but with a correlation function whose exponential decay has also a spatial modulation. In this phase the asymptotic correlation function in the bulk is conveniently parametrized for large spin separation $d$ by the functional form

$$C^{zz}(d) = \langle \sigma_i^z \sigma_{i+d}^z \rangle \sim c_0 e^{-d/r} \cos(\pi q d + \varphi),$$  \hspace{1cm} (2)

with $r$ and $q$ being functions of $B$ and $\kappa$. 
The modulation parameter \( q(B, \kappa) \) vanishes at \( B = B_{c,2}(\kappa) \) with a certain exponent \( \beta_q \)

\[
q(B, \kappa) \sim A(B - B_{c,2}(\kappa))^{\beta_q}, \quad B \ll B_{c,2}(\kappa). \quad (3)
\]

The critical line \( B = B_{c,2}(\kappa) \) is known as a disorder line \( 2 \) (see also \( 3 \) for a different definition).

The region \( \kappa > 1/2 \) is much more complicated. At low \( B \) the ground state is in a so-called antiphase with typical spin configuration \( \uparrow \uparrow \downarrow \downarrow \cdots \). Increasing the magnetic field one expects to observe a first transition to a disordered phase with algebraically decaying \( C^2 \) (the floating phase) followed by a final transition to the asymptotic paramagnetic phase, i.e., the unique high temperature phase in the original 2d statistical model. The numerical data in this region are controversial and the size of the floating phase is not clear being possibly zero \( 6 \).

In this Letter, we shall be concerned with the \( \kappa < 1/2 \) region only. For simplicity, we shall denote this region by LFR (low frustration region). In the LFR, there is a general consensus about the phase diagram, although only at the qualitative level, i.e., with large variations due to the various approximation employed in its calculation.

Remarkably, the TAM model can be solved exactly on a critical line in the LFR called the Peschel-Emery one-dimensional line (ODL) \( 10 \). The spin correlation decays exponentially on the ODL which is immersed in the paramagnetic phase. Little is known analytically off the ODL due to the very tricky nature of the solution. It is still a conjecture that the ODL is indeed the disorder line and that therefore

\[
B_{c,2}/J_1 = B_{c,2}^{PE}/J_1 \equiv \kappa - \frac{1}{4\kappa}. \quad (4)
\]

The conjecture is compatible with the numerical simulations of the TAM model. However, the agreement \( B_{c,2} = B_{c,2}^{PE} \) is valid at not more than about 20\% accuracy along the line.

The aim of this Letter is precisely to give a numerical proof with good accuracy of this conjecture. As a byproduct we also determine the unknown exponent \( \beta_q \).

A detailed analysis of the quantum ANNNI model can be found in \( 11 \). The accuracy of the results is poor because of the small considered lattices with less than 10 sites. Another interesting approach is described in \( 12 \) where an effective Hamiltonian is proposed allowing a considerable reduction of the Hilbert space. Systems up to 32 sites long can be treated, but the approximation is valid only near \( \kappa = 1/2 \).

A more recent numerical analysis of the LFR is \( 13 \) where the ferromagnetic-paramagnetic Ising transition is analyzed by combining Finite Size Scaling with exact diagonalization of short chains with no more than 10 sites.

Here we present a study of the model with higher accuracy and much larger lattices by means of the Density Matrix Renormalization Group (DMRG) algorithm \( 14 \).

![FIG. 1: Finite Size Scaling analysis of \( L\Delta_L(\kappa, B) \) at \( \kappa = 0.3 \).](image)

Nowadays, this method appears to be the natural choice for one-dimensional quantum spin chains.

We have implemented the finite size version of the DMRG algorithm computing the two lowest levels \( E_{0,1} \) and the energy gap \( \Delta = E_1 - E_0 \). The algorithm results are very stable when more than 80 states are kept in the block Hamiltonians. In practice the numerical error on \( \Delta \) is at the level of the machine precision.

For several lattice sizes \( L \) of order \( 10^2 \) and various frustration ratios \( \kappa \), we have computed the scaled energy gap \( L\Delta_L(\kappa, B) \). The crossing of the associated curves as a function of \( B \) at fixed \( \kappa \) is a finite size estimate of the ferromagnetic critical field \( B_{c,1}^{(L)}(\kappa) \). As an example, we show in Fig. \( 11 \) our results at \( \kappa = 0.3 \). We have determined the crossing point between the curves associated to a certain \( L \) and \( L+10 \). We expect \( B_{c,1}^{(L)} \to B_{c,1}(\kappa) \) as \( L \to \infty \) with algebraic corrections in \( 1/L \) \( 13 \).

We show in Fig. \( 2 \) the finite size crossing field plotted as a function of \( x = 1/(L + 10) \) which is the most convenient variable to extrapolate our \( (L, L+10) \) crossings. Indeed, the fitting function \( a + bx^2 + cx^3 \) gives a very good \( \chi^2 \) of about \( 10^{-11} \). The results for all the considered \( \kappa \) are collected in Tab. \( 11 \) where we also show (when available) the analogous results from \( 12 \).

These are obtained on small lattices crossing \( L \) with a fixed \( L = 4 \). This is at most an estimate of \( B_{c,1} \). Tab. \( 11 \) reports also \( B_{c,1} \) which is obtained from the vanishing of the gap at second order in \( B \) \( 10 \), and is defined by

\[
1 + 2\kappa = \frac{B_{c,1}}{J_1} + \frac{\kappa}{2(1+\kappa)} \left( \frac{B_{c,1}}{J_1} \right)^2. \quad (5)
\]

In principle, it is possible to determine \( B_{c,1} \) directly in the infinite size limit by using the infinite lattice version of the DMRG algorithm. We show in Fig. \( 3 \) the result of such a procedure at \( \kappa = 0.4 \). The result for \( B_{c,1} \) is...
fully consistent with the FSS analysis. Also, the exponent \( \nu = 1 \) which governs the vanishing of the mass gap is very clear at \( L = \infty \). For the other values of \( \kappa \) we have preferred to avoid the infinite size algorithm since it is known that it can fail when the phase structure is complicated [16]. From Tab. (I) we see that the DMRG estimate \( B_{c,1}^{\text{DMRG}} \) and the results of [13] are globally similar and slightly below the approximation \( \tilde{B}_{c,1} \), especially at large \( |\kappa - 1/2| \). The value from [13] at \( \kappa = 0.4 \) is somewhat away from the common values of \( B_{c,1}^{\text{DMRG}} \) and \( \tilde{B}_{c,1} \).

After the determination of the ferromagnetic-paramagnetic Ising transition, we studied \( B_{c,2}(\kappa) \) and the critical behavior of the modulation \( q \). We have computed by the DMRG algorithm the spin correlation \( C^{zz} \) on lattices large compared to the correlation length \( r \) appearing in Eq. (2). In practice, \( L = 40 \) is enough in all the considered cases. The critical behaviour of \( q(B) \) is shown in Fig. (4) for \( \kappa = 0.3 \). The vanishing of \( q^2 \) is linear in \( B - B_{c,2} \). The modulation parameter vanishes with exponent \( \beta_q = 1/2 \). The critical field \( B_{c,2} \) coincides with the Peschel-Emery value [10] with high accuracy.

We have repeated the analysis for \( \kappa = 0.15, 0.2, 0.25, 0.35, 0.4 \), finding always a very good agreement. The agreement at small frustration is remarkable. From the point of view of the disorder line the next-nearest-neighbor coupling \( J_2 \) is a singular perturbation with \( B_{c,2} \to \infty \) in the isotropic Ising limit \( \kappa \to 0 \). We remark that it is nontrivial to extend the calculation of [10] off the one-dimensional line to prove rigorously that the one-dimensional line is the disorder line. Indeed, the only

### Table I

FIG. 2: Extrapolation of the Finite Size Scaling crossing estimator \( B_{c,1}^{(L)} \cdot \kappa = 0.3 \) and \( L = 10, 20, \ldots, 80 \).

FIG. 3: Finite Size Scaling analysis at \( \kappa = 0.4 \). The left plot includes the data obtained with the infinite size DMRG algorithm and labeled \( L = \infty \).

FIG. 4: \( B \) dependence of the squared modulation parameter \( q^2 \) at \( \kappa = 0.3 \). The fit is performed on the leftmost points near the critical point.
analytic insight in this direction is the analysis in [17] where the ODL is proved to be the disorder line, but only mapping the initial $S = 1/2$ spin chain into a dual spin $T = 1/2$ chain and taking the $T \to \infty$ limit.

Our results for $B_{c,2}$ are also summarized in Tab. II together with the Peschel-Emery value. In Fig. 5 we plot the final phase diagram as determined by our DMRG simulations.

In conclusion, we have shown that a DMRG analysis of the quantum ANNNI model provides strong numerical support to the conjecture that the Peschel-Emery ODL is actually the disorder line. Also, the critical exponent governing the vanishing of the modulation at the disorder transition is $\beta_q = 1/2$.

A natural extension of this work concerns the DMRG study of the region $\kappa > 1/2$, which requires much larger lattices to analyze the slow algebraic decay of the spin correlation functions in the would-be floating phase.
