Abstract. In this paper we review some recent progress in the field of non-equilibrium linear response theory. We show how a generalization of the fluctuation dissipation theorem can be derived for Markov processes, and discuss the Cugliandolo–Kurchan fluctuation dissipation relation for ageing systems and the theorem by Franz et al relating static and dynamic properties. We then specialize to phase ordering systems, examining the scaling properties of the linear response function and how these are determined by the behaviour of topological defects. We discuss how the connection between statics and dynamics can be violated in these systems at the lower critical dimension or due to stochastic instability.

Keywords: coarsening processes (theory)
1. Introduction

The fluctuation dissipation theorem [1] (FDT) is one of the fundamental accomplishments of linear response theory applied to equilibrium systems. According to the FDT a response function $\chi$ describing the effects of a small perturbation exerted on a system is linearly related, via the equilibrium temperature $T$, to a correlation function $C$ of the system in the absence of the perturbation. In the language of magnetic systems, which we shall adopt in the following, one usually considers the application of an external magnetic field $h$, and $\chi$ is the magnetic susceptibility.

In recent years there has been considerable interest, arising in different fields such as turbulent fluids [2], disordered, glassy [3]–[5] and ageing systems [6], in the generalization of the results of linear response theory to out of equilibrium systems. Unlike for equilibrium statistical mechanics, where a well founded and controlled theory is available, there is not nowadays a theorem of generality comparable to the FDT’s for non-equilibrium states. Nevertheless, some interesting progress has been made in understanding some particular aspects of non-equilibrium linear response theory, some of which will be discussed in this paper.

A first basic question regards the possibility of generalizing the FDT. Namely, the question is whether even away from equilibrium it is still possible to relate the response function to properties of the unperturbed dynamics, possibly via correlation functions. A positive answer to this question exists when the time evolution is Markovian and described by a differential equation of the Langevin type [7] or for systems described by a master
equation [8]. In this case, the response function is related to correlation functions of the unperturbed systems, which, however, are not just the correlation $C$ involved in equilibrium. These results are particularly important since they allow the study of the response function without considering the perturbed system, which is generally more complicated.

Once a relation between response and correlations is established, at least in the restricted framework of Markov processes, the natural question is which piece of information, if any, can be learned from it about the non-equilibrium state. In equilibrium the linear relation between $\chi$ and $C$ is universal, and the coefficient $d\chi/dC$ entering this relation is $T$. In the restricted area of ageing systems it has been shown that the $\chi(C)$ relation still bears a universal character, although weaker than in equilibrium. This is because the theorem by Franz, Mézard, Parisi and Peliti [9] connects $\chi(C)$ to the equilibrium probability distribution of the overlaps $P_{eq}(q)$ and different statistical mechanical systems can be classified into a few universality classes on the basis of their $P_{eq}(q)$ according to the replica symmetry breaking character of the ground state [10]. Moreover, $d\chi/dC$ can be interpreted as an effective temperature [4].

These results promoted linear response theory as an important tool for investigating the non-equilibrium behaviour or even the structure of equilibrium states of complex systems, such as spin glasses, which are hard to equilibrate, where $P_{eq}(q)$ can be better inferred from a non-equilibrium measurement of $\chi(C)$. However, in order for these studies to be sound, a basic understanding of the out of equilibrium behaviour of the response function is required. Instead, at the level of coarsening systems, which can be considered as the simplest paradigm of ageing phenomenon, where a satisfactory general analytic description can nowadays be given by means of exactly solvable models or approximate theories, the scaling properties of the response function are already non-trivial and still far from being understood. Notably, the statics–dynamics connection stated by the theorem [9] is not always fulfilled in coarsening systems.

In this paper we review some recent progress in the field of non-equilibrium linear response theory. The focus is mainly on ageing systems and, in particular, on phase ordering, which, because of its relative simplicity, is better suited for a thorough analysis. The paper is organized as follows. Sections 2–5 are of a general character; here we fix up the basic definitions, discuss the generalization of the FDT for Markov processes, introduce the fluctuation dissipation relation and review the theorem [9] which links statics to dynamics. In section 6 some of the concepts introduced so far are specialized to the case of phase ordering kinetics. After a general description of the dynamics in section 6.1, the behaviour of the response function is reviewed in section 6.2. In particular, in section 6.2.1 the scaling properties of $\chi$ are discussed and in section 6.2.2 it is shown how, in the case of a scalar order parameter, the exponents can be related to the roughening properties of the interfaces. Section 6.3 contains a discussion of how the connection between statics and dynamics is realized or violated in coarsening systems. Some open problems are enumerated in section 7 and the conclusions are drawn.

2. Basic definitions

Let us consider a system described by the Hamiltonian $H_0$. The autocorrelation function of a generic observable $O$, between the two times $s$ and $t \geq s$, is

$$C(t, s) = \langle O(t)O(s) \rangle,$$

(1)

doi:10.1088/1742-5468/2007/07/P07002

3
where $\langle \cdots \rangle$ is an ensemble average. Switching on an impulsive perturbation $h(s)$ at time $s$ which changes the Hamiltonian $\mathcal{H} \to \mathcal{H} + \Delta \mathcal{H} = \mathcal{H} - h \mathcal{O}$, the linear (impulsive) response function is given by

$$R(t, s) = \left. \frac{\partial \langle \mathcal{O}(t) \rangle}{\partial h(s)} \right|_{h=0}.\tag{2}$$

The integrated response function, or dynamic susceptibility, is

$$\chi(t, s) = \int_s^t R(t, t') \, dt'\tag{3}$$

and corresponds to the response to a perturbation switched on from $s$ onwards.

In equilibrium, time translation invariance (TTI) holds, so that the two time quantities introduced above depend only on the time difference $\tau = t - s$. The FDT reads

$$TR(\tau) = -\frac{dC(\tau)}{d\tau},\tag{4}$$

where $T$ is the temperature, or, equivalently, for the integrated response,

$$T\chi(\tau) = C(\tau = 0) - C(\tau).\tag{5}$$

### 3. Off-equilibrium generalization of the fluctuation dissipation theorem for Markov processes

Consider a system with an order parameter field $\phi(\bar{x})$ evolving with the Langevin equation of motion

$$\frac{\partial \phi(\bar{x}, t)}{\partial t} = B[\phi(\bar{x}, t)] + \eta(\bar{x}, t)\tag{6}$$

where $B[\phi(\bar{x}, t)]$ is the deterministic force and $\eta(\bar{x}, t)$ is a white, zero-mean Gaussian noise. In this framework a generalization of the FDT was derived in [7]. Let us recall the basic elements; we refer the reader to [7] for further details. From equation (6), the linear response function is simply computed as the correlation function of the order parameter with the noise

$$2TR(t, s) = \langle \phi(\bar{x}, t) \eta(\bar{x}, s) \rangle\tag{7}$$

where $T$ is the temperature of the thermal bath and $t \geq s$ by causality. It is straightforward to recast the above relation in the form

$$TR(t, s) = \frac{1}{2} \frac{\partial C(t, s)}{\partial s} - \frac{1}{2} \frac{\partial C(t, s)}{\partial t} - A(t, s)\tag{8}$$

where

$$C(t, s) = \langle \phi(\bar{x}, t) \phi(\bar{x}, s) \rangle - \langle \phi(\bar{x}, t) \rangle \langle \phi(\bar{x}, s) \rangle\tag{9}$$

and

$$A(t, s) \equiv \frac{1}{2} \{ \langle \phi(\bar{x}, t) B[\phi(\bar{x}, s)] \rangle - \langle B[\phi(\bar{x}, t)] \phi(\bar{x}, s) \rangle \}.\tag{10}$$

\textit{doi:10.1088/1742-5468/2007/07/P07002}
is the so called asymmetry. Equation (8), or (7), qualifies as an extension of the FDT out of equilibrium, since in the right-hand side there appear unperturbed correlation functions. When time translation and time inversion invariance hold, so that \( A(t, s) = 0 \) and \( \partial C(t, s)/\partial t = -\partial C(t, s)/\partial s \), this reduces to the equilibrium FDT (4). Let us mention that this equation holds [8] in the same form both for conserved order parameter (COP) and non-conserved order parameter (NCOP) dynamics [11].

The next interesting question is that of whether one can do the same also in the case of discrete spin variables, where the kinetics is described by a master equation, there is no stochastic differential equation and, therefore, equation (7) is not applicable. A first approach to this problem was undertaken in [12, 13, 15, 16] where a relation between the \( \partial C \) and \( \partial p \) functions. When time translation and time inversion invariance hold, so that this equation holds [8] in the same form both for COP (spin exchange) and NCOP (spin flip) dynamics, can be derived also in this case.

Let us consider a system of Ising spins \( \sigma_i = \pm 1 \) executing a Markovian stochastic process. The generalization to \( q \)-state spins, as in the Potts or clock model, is straightforward. The problem is how to compute the linear response \( R(t, s) \) of the spin at the site \( i \) and at the time \( t \) to an impulse of external field at an earlier time \( s \) and at the same site \( i \). Let

\[
h_j(t) = \h \delta_{i,j} \theta(t - s) \theta(s + \Delta t - t)
\]

be the magnetic field at the \( i \)th site acting during the time interval \([s, s + \Delta t]\), where \( \theta \) is the Heaviside step function. The response function is then given by [12, 13]

\[
R(t, s) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \left. \frac{\partial \langle \sigma_i(t) \rangle}{\partial h_j(s)} \right|_{h=0}
\]

where

\[
\left. \frac{\partial \langle \sigma_i(t) \rangle}{\partial h_j(s)} \right|_{h=0} = \sum_{[\sigma], [\sigma'], [\sigma'']} \sigma_i \rho([\sigma], t| [\sigma'], s + \Delta t) \left. \frac{\partial p^h([\sigma'], s + \Delta t| [\sigma''], s)}{\partial h_j} \right|_{h=0} p([\sigma''], s)
\]

and \([\sigma]\) are spin configurations.

Let us concentrate on the factor containing the conditional probability in the presence of the external field \( p^h([\sigma'], s + \Delta t| [\sigma''], s) \). In general, the conditional probability for \( \Delta t \) sufficiently small is given by

\[
p([\sigma], t + \Delta t| [\sigma'], t) = \delta_{[\sigma], [\sigma']} + w([\sigma'] \rightarrow [\sigma]) \Delta t + O(\Delta t^2),
\]

where we have used the boundary condition \( p([\sigma], t| [\sigma'], t) = \delta_{[\sigma], [\sigma']} \). Furthermore, the transition rates must verify the detailed balance

\[
w([\sigma'] \rightarrow [\sigma]) \exp(-\mathcal{H}[\sigma]/\mathcal{T}) = w([\sigma'] \rightarrow [\sigma]) \exp(-\mathcal{H}[\sigma']/\mathcal{T}),
\]

where \( \mathcal{H}[\sigma] \) is the Hamiltonian of the system.

Introducing the perturbing field as an extra term \( \Delta \mathcal{H}[\sigma] = -\sigma_j h_j \) in the Hamiltonian, to linear order in \( \h \) the most general form of the perturbed rate of the transition
Fluctuation dissipation relations far from equilibrium

where $M([\sigma],[\sigma'])$ is an arbitrary function of order $h/T$ symmetric with respect to the exchange $[\sigma] \leftrightarrow [\sigma']$, and $w^0([\sigma] \rightarrow [\sigma'])$ are unspecified unperturbed transition rates, which satisfy detailed balance. In the following, for simplicity, we shall take $M([\sigma],[\sigma']) = 0$. Implications of this choice, which corresponds to a specification of the perturbed transition rates, are discussed in [8].

Inserting equations (14), (16) in equation (13), and using the time translational invariance of the conditional probability $p([\sigma], t|[\sigma'], s+\Delta t) = p([\sigma], t-\Delta t|[\sigma'], s)$, after some manipulations the response function (12) can be written as

$$TR(t, s) = \frac{1}{2} \frac{\partial C(t, s)}{\partial s} - \frac{1}{2} E(t, s)$$

where

$$C(t, s) = \langle \sigma_i(t) \sigma_i(s) \rangle$$

is the autocorrelation function,

$$E(t, s) = \langle \sigma_i(t) B_i(s) \rangle$$

and

$$B_i = - \sum_{[\sigma'']} (\sigma_i - \sigma''_j)w^0([\sigma] \rightarrow [\sigma'']).$$

For the dynamic susceptibility one has

$$T\chi(t, s) = \frac{1}{2} [C(t, t) - C(t, s)] - \frac{1}{2} \int_s^t E(t, t') dt'.$$

It is interesting to observe that equation (17) is completely analogous to equations (8) and (10). In fact, it can be easily shown that

$$\frac{d\langle \sigma_i(t) \rangle}{dt} = \langle B_i(t) \rangle$$

and that

$$\frac{\partial C(t, s)}{\partial t} - \langle B_i(t) \sigma_i(s) \rangle = 0.$$

Subtracting this from equation (17) we finally arrive at equation (8) where $A(t, s)$ is given by

$$A(t, s) = \frac{1}{2} [\langle \sigma_i(t) B_i(s) \rangle - \langle B_i(t) \sigma_i(s) \rangle].$$

Equations (8) and (24) are the main result of this section. They are identical to equations (8) and (10) for Langevin dynamics, since the observable $B$ entering the asymmetries (10) and (24) plays the same role in the two cases. In fact, equation (22) is the analogue of

$$\frac{\partial \langle \phi(\vec{x}, t) \rangle}{\partial t} = \langle B[\phi(\vec{x}, t)] \rangle$$

obtained from equation (6) after averaging over the noise.

doi:10.1088/1742-5468/2007/07/P07002
In summary, equation (8) is a relation between the response function and correlation functions of the unperturbed kinetics, which generalizes the FDT. Equation (8) applies to a wide class of systems: besides being obeyed by soft and hard spins, it holds for both COP and NCOP dynamics. Moreover, as is clear by its derivation, it does not require any particular assumption on the Hamiltonian nor on the form of the unperturbed transition rates, and can be easily generalized [14] to intrinsically non-equilibrium systems where the transition rates do not obey detailed balance. Finally, let us briefly discuss (for details see [8]) the differences between the results discussed so far and those obtained by Chatelain [12], Ricci-Tersenghi [15], Diezeman [16] and Crisanti and Ritort [13]. In these papers also, in fact, the response function is related to unperturbed correlation functions but, unlike those appearing in equations (17), (21), these functions must be computed on a system which evolves with an ad hoc kinetic rule, different from that of the original unperturbed system, which is introduced with the sole purpose of evaluating the response function. It can be shown that this corresponds, in the averaging procedure, to considering only a subset of trajectories of the original unperturbed system. Therefore, although the results of [12,13,15,16] are important, both for computational and analytical calculations, they cannot be regarded as generalizations of the FDT in the sense of equation (8) because the response function is not related to correlation functions of the unperturbed system.

4. Fluctuation dissipation relation

In section 3 we have shown that in the cases considered the integrated response function out of equilibrium is not only related to the autocorrelation function but also to the correlation $E(t, s)$ by means of equation (21). A very useful tool for the study of slow relaxation phenomena has been introduced by Cugliandolo and Kurchan [3] through the off-equilibrium fluctuation dissipation relation (FDR). This was introduced as a direct relation between $\chi(t, s)$ and $C(t, s)$ as follows: given that $C(t, s)$ is a monotonically decreasing function of $t$, for fixed $s$ it is possible to invert it and write

$$\chi(t, s) = \tilde{\chi}(C(t, s), s).$$

Then, if for a fixed value of $C(t, s)$ there exists the limit

$$\lim_{s \to \infty} \tilde{\chi}(C, s) = S(C),$$

the function $S(C)$ gives the fluctuation dissipation relation. In the particular case of equilibrium dynamics, the FDT is recovered and $S(C) = [C(\tau = 0) - C]/T$. Originally introduced in the study of the low temperature phase of spin glass mean field models, the fluctuation dissipation relation has been found in many other instances of slow relaxation [13].

5. Statics from dynamics

One of the main reasons for the interest in the fluctuation dissipation relation is that it may provide a link between dynamic and static properties, and in particular with the equilibrium overlap probability function

$$P(q) = \frac{1}{Z^2} \sum_{[\sigma], [\sigma']} \exp \left\{ -\frac{1}{T} [H([\sigma]) + H([\sigma'])] \right\} \delta(Q([\sigma], [\sigma']) - q)$$

doi:10.1088/1742-5468/2007/07/P07002
where $Z$ is the partition function and $Q([\sigma],[\sigma']) = 1/N \sum_i \sigma_i\sigma'_i$ is the overlap between two configurations $[\sigma]$ and $[\sigma']$. For slowly relaxing systems this is established in general by a theorem by Franz et al [9] stating that

1. if $S(C)$ exists,
2. if $\lim_{t \to \infty} \chi(t,s) = \chi_{eq}$, the equilibrium susceptibility,

then the off-equilibrium fluctuation dissipation relation can be connected to equilibrium properties through

$$-T \frac{d^2S(C)}{dC^2} \bigg|_{C=q} = \tilde{P}(q),$$

where $\tilde{P}(q)$ is the overlap probability function in the equilibrium state obtained in the limit in which the perturbation responsible of $\chi(t,s)$ is made to vanish. The relation between $\tilde{P}(q)$ and the unperturbed overlap function $P(q)$ must be considered carefully. This implies the notion of stochastic stability [17]. In a stochastically stable system the equilibrium state in the presence of a perturbation, in the limit of a vanishing perturbation, is the same as that of the corresponding unperturbed system. Notice that, while stochastic stability is always expected for ergodic systems, this property is far from being trivial when more ergodic components are present, as is easily understood by considering the Ising model perturbed by an external magnetic field. If a system is stochastically stable then $P(q) = \tilde{P}(q)$. A milder statement of stochastic stability is that $\tilde{P}(q)$ coincides with $P(q)$ up to the effects of a global symmetry which might be removed by the perturbation. For instance, in the Ising case, where the perturbation breaks the up–down symmetry, defining

$$\hat{P}(q) = 2\theta(q)P(q),$$

the system is stochastically stable in the sense that $\hat{P}(q) = \tilde{P}(q)$. In conclusion, if the system is stochastically stable, equation (29) holds with $\hat{P}(q)$ on the right-hand side, establishing a connection between the FDR and the equilibrium properties of the unperturbed state. On the other hand, if the system is not stochastically stable, $\tilde{P}(q)$ is not related either to $P(q)$ or to $\hat{P}(q)$. As we shall see in section 6.3.2, this is the case for the mean spherical model.

With this link between statics and dynamics one can translate [10] to the dynamics of the usual classification of complex systems on the basis of the kind of replica symmetry breaking [18]. According to this categorization a first class of systems are those whose low temperature phase is characterized by two pure states which are related by a global spin inversion. As will be discussed in section 6.3, these systems without replica symmetry breaking are described by a $\tilde{P}(q)$ with a single $\delta$ function centred on the Edwards–Anderson order parameter $q_{EA}$ (the squared magnetization, in ferromagnetic systems), and their FDR, according to equation (29) is a broken line with a horizontal part. This situation is shown in figure 1, upper part (I). A second class of systems is those where a transition with a single step of replica symmetry breaking occurs, as for $p$ spins with $p > 2$ in mean field, binary mixtures of soft spheres [19] or Lennard-Jones mixtures [20]. In these systems $\tilde{P}(q)$ is made of two $\delta$ functions, one centred at the origin and the other around a finite $q_{EA}$. Their FDR is made of two straight lines with finite slopes, as shown.

doi:10.1088/1742-5468/2007/07/P07002
Figure 1. Classification of systems according to their $\tilde{P}(q)$ (left) or, equivalently, $S(C)$ (right), following [10]. Bold arrows represent $\delta$ functions. Rows denoted as I, II, and III describe the three classes of systems discussed in the text.

in figure 1 in the central panel (II). Systems such as the Edwards–Anderson model in the mean field fall into a third category, for which $\tilde{P}(q)$ is different from zero for a whole range $q \in [0, q_{EA}]$ with a delta function on $q_{EA}$. These systems have a FDR with a straight line and a bending curve, as shown in figure 1, lower part (III).

6. Phase ordering

Phase ordering [11] is usually regarded as the simplest instance of slow relaxation, where concepts like scaling and ageing, which are the hallmarks of glassy behaviour [22], can be more easily investigated. However, besides the similarities there are also fundamental differences [21] which require keeping the phase ordering distinct from the out of equilibrium behaviour in glassy systems, both disordered and non-disordered. The main source of the differences is the simplicity of the free energy landscape in the case of phase ordering compared to the complexity underlying glassy behaviour.

Besides the obvious motivation that the basic, paradigmatic cases need to be thoroughly understood, an additional reason for studying phase ordering, among others, is that in some cases the existence of complex slow relaxation is identified through the exclusion of coarsening. An example comes from the long standing controversy about the nature of the low temperature phase of finite dimensional spin glasses. One argument in favour of replica symmetry breaking is that the observed behaviour of the response function is incompatible with coarsening [9,10]. This might well be the case; however, for the argument to be sound, the understanding of the out of equilibrium behaviour of the response function during phase ordering needs to be up to the level that such a delicate issue demands.

In this section we present an overview of the accurate investigation of the response function in phase ordering that we have carried out in the last few years. Focusing on the integrated response function (3), or zero-field cooled magnetization (ZFC) in the language
of magnetic systems, it will be argued that the response function in phase ordering systems is not as trivial as it is believed to be and, after all, it is not the quantity best suited to highlighting the differences between systems with and without replica symmetry breaking. In fact, as discussed in sections 6.3, 6.3.2, there are cases in which phase ordering, and therefore a replica symmetric low temperature state, are compatible with a non-trivial ZFC. When this happens there is no connection between static and dynamic properties. Phase ordering systems offer examples of two distinct mechanism for the lack of this important feature of slowly relaxing systems, stochastic instability and the vanishing of the scaling exponent of ZFC.

Let us first briefly recall the main features of a phase ordering process. Consider a system, like a ferromagnet, with order parameter (vector or scalar, continuous or discrete) \( \phi(\vec{x}) \) and Hamiltonian \( \mathcal{H}[\phi(\vec{x})] \) such that below the critical temperature \( T_C \) the structure of the equilibrium state is simple. For example, in the scalar case, there are two pure ordered states connected by inversion symmetry. The form of the Hamiltonian can be taken as the simplest compatible with such a structure, like the Ginzburg–Landau–Wilson one for continuous spins or the nearest neighbour Ising Hamiltonian for discrete spins.

Let us generalize the definition (9) to the space and time dependent correlation function

\[
C(\vec{r}, t, s) = \langle \phi(\vec{x}, t) \phi(\vec{x}', s) \rangle - \langle \phi(\vec{x}, t) \rangle \langle \phi(\vec{x}', s) \rangle
\]

(31)

where the average is taken over initial condition and thermal noise, and \( \vec{r} = \vec{x} - \vec{x}' \). We use the notation \( C(\vec{r} = 0, t, s) = C(t, s) \), and similarly for the response functions defined below. The linear response function conjugated to \( C(\vec{r}, t, s) \) is given by

\[
R(\vec{r}, t, s) = \left. \frac{\delta \langle \phi(\vec{x}, t) \rangle}{\delta h(\vec{x}', s)} \right|_{h=0},
\]

(32)

where \( h(\vec{x}, t) \) is a space–time dependent external magnetic field and the integrated response function is defined by

\[
\chi(\vec{r}, t, s) = \int_s^t ds \: R(\vec{r}, t, s).
\]

(33)

### 6.1. Dynamics over phase space: equilibration versus falling out of equilibrium

For a temperature \( T \) below \( T_C \), in the thermodynamic limit, the phase space \( \Omega = \{ [\phi(\vec{x})] \} \) may be regarded as the union of three ergodic components [23] \( \Omega = \Omega_+ \cup \Omega_- \cup \Omega_0 \), where \( \Omega_\pm \) and \( \Omega_0 \) are the subsets of configurations with magnetization \( \lim_{V \to \infty} (1/V) \int_V d\vec{x} \phi(\vec{x}) \) positive, negative and vanishing, respectively. Denoting by \( \rho_\pm[\phi(\vec{x})] \) the two broken symmetry pure states, whose typical configurations are schematically represented in figure 2, all equilibrium states are convex linear combinations of \( \rho_\pm \). The \( \Omega_\pm \) components are the domains of attraction of the pure states with \( \rho_\pm(\Omega_\pm) = \rho_- (\Omega_-) = 1 \) and \( \Omega_0 \) is the border between them, with zero measure in any of the equilibrium states.

When ergodicity is broken, quite different behaviours may arise [23] depending on the initial condition \( \rho_0(\phi(\vec{x})) = \rho([\phi(\vec{x})], t = 0) \). Here, we consider the three cases relevant for what follows, assuming that there are not explicit symmetry breaking terms in the equation of motion:
Figure 2. Typical configurations of a binary system after equilibration to the pure states $\rho_+[\phi(\vec{x})]$ or $\rho_-[\phi(\vec{x})]$ (left and right panels).

(1) **Equilibration to a pure state.** If $\rho_0(\Omega_+)$ = 1 or $\rho_0(\Omega_-)$ = 1, in the time evolution, configurations are sampled from either one of $\Omega_\pm$ and $\rho([\phi(\vec{x})], t)$ equilibrates to the time independent pure state $\rho_\pm[\phi(\vec{x})]$ within the finite relaxation time $t_{eq} \sim \xi^z$, where $\xi$ is the equilibrium correlation length and $z$ is the dynamic exponent. The correlation functions are the same for the two ergodic components and, after equilibration, are time translation invariant:

$$C_{st}(\vec{r}, \tau) = \langle \phi(\vec{x}, t)\phi(\vec{x}', s) \rangle_\pm - M^2 \quad (34)$$

where $\langle \phi(\vec{x}) \rangle_\pm = \pm M$ is the spontaneous magnetization. For large distances $r \gg \xi$ and time separations $t - s \gg t_{eq}$, the clustering property $\langle \phi(\vec{x}, t)\phi(\vec{x}', s) \rangle_\pm = \langle \phi(\vec{x}, t) \rangle_\pm \langle \phi(\vec{x}', s) \rangle_\pm$ is obeyed and the correlations decay to zero, as required by ergodicity (see figure 6).

(2) **Equilibration to the Gibbs state.** If $\rho_0(\Omega_+) = \rho_0(\Omega_-) = 1/2$, then configurations are sampled evenly from the two disjoint components $\Omega_+$ and $\Omega_-$. The probability density $\rho([\phi(\vec{x})], t)$ equilibrates now to the Gibbs state $\rho_G[\phi(\vec{x})]$ with the same relaxation time $t_{eq}$ as in the relaxation to the pure states. Broken ergodicity shows up in the large distance and in the large time properties of the correlation function. After equilibration, one has

$$C_G(\vec{r}, \tau) = C_{st}(\vec{r}, \tau) + M^2 \quad (35)$$

from which it follows that correlations do not vanish asymptotically or that the clustering property is not obeyed:

$$\lim_{r \to \infty} C_G(\vec{r}, \tau) = \lim_{\tau \to \infty} C_G(\vec{r}, \tau) = M^2 \quad (36)$$

(3) **Falling out of equilibrium over the border** [24,25]. If $\rho_0(\Omega_0) = 1$, for the infinite system $\rho(\Omega_0, t) = 1$ also at any finite time after the quench. Namely, the system does not equilibrate, since in any equilibrium state the measure of $\Omega_0$ vanishes. Phase ordering corresponds to this case. In fact, the system is initially prepared in equilibrium at very high temperature (for simplicity $T_I = \infty$) and at the time $t = 0$ is suddenly quenched to a final temperature $T$ below $T_C$. In the initial state the probability measure over phase space is uniform, $\rho_0[\phi(\vec{x})] = 1/|\Omega|$, implying that the initial configuration at

doi:10.1088/1742-5468/2007/07/P07002
Figure 3. Configurations of a coarsening system at different times $t_1 < t_2 < t_3 < t_4$.

$t = 0$ belongs almost certainly to $\Omega_0$, since with a flat measure $|\Omega_0|$ is overwhelmingly larger than $|\Omega_\pm|$.

The morphology of typical configurations visited as the system moves over $\Omega_0$ is a patchwork of domains of the two competing equilibrium phases, which coarsen as the time goes on, as schematically shown in figure 3. The typical size of domains grows with the power law $L(t) \sim t^{1/z}$, where $z = 2$ (independent of dimensionality) for dynamics with non-conserved order parameter [11], as will be considered here. The sampling of configurations of this type is responsible for the peculiar features of phase ordering. At a given time $s$ there remains defined a length $L(s)$ such that for space separations $r \ll L(s)$ or for time separations $t - s \ll s$ intra-domain properties are probed. Then, everything goes as in case 2 of the equilibration to the Gibbs state, ergodicity looks broken and the correlation function obeys equation (35). Conversely, for $r \gg L(s)$ or $t/s \gg 1$, inter-domain properties are probed, ergodicity is restored (as it should be, since evolution takes place within the single ergodic component $\Omega_0$) and eventually the correlation function decays to zero. However, the peculiarity is that if the limit $s \to \infty$ is taken before $r \to \infty$, in the space sector ergodicity remains broken, giving rise, for instance, to the growth of the Bragg peak in the equal time structure factor.

According to this picture, the correlation function can be written as the sum of two contributions:

$$C(\vec{r}, t, s) = C_{st}(\vec{r}, \tau) + C_{ag}(\vec{r}, t, s)$$
where the first one is the stationary contribution of equation (34) describing equilibrium fluctuations in the pure states and the second one contains all the out of equilibrium information. The latter one is the correlation function of interest in the theory of phase ordering where, in order to isolate it, zero-temperature quenches are usually considered as a device to eliminate the stationary component. It is now well established that $C_{ag}(\vec{r}, t, s)$ obeys scaling in the form [26]

$$C_{ag}(\vec{r}, t, s) = \hat{C}(r/L(s), t/s)$$  \hspace{1cm} (38)

with $\hat{C}(x, y) = M^2$ for $x < 1$ and $y \sim 1$, while

$$\hat{C}(r/L(s), t/s) \sim (t/s)^{-\lambda/z} h(r/L(s))$$  \hspace{1cm} (39)

for large time separation [11], where $\lambda$ is the Fisher–Huse exponent.

### 6.2. Zero-field cooled magnetization

Let us next consider what happens when a time independent external field $h(\vec{x}, s)$ is switched on at the time $s$. To linear order the expectation value of the order parameter at the later time $t$ is given by

$$\langle \phi(\vec{x}, t) \rangle_h = \langle \phi(\vec{x}, t) \rangle_0 + \int d\vec{x}' \int ds R(\vec{x} - \vec{x}', t, s)h(\vec{x'}, s).$$  \hspace{1cm} (40)

If $h(\vec{x}, s) = h(\vec{x})\theta(t - s)$ is a random field switched on and kept constant from $s$ onwards, with expectations

$$\langle h(\vec{x}) \rangle = 0$$

$$\langle h(\vec{x})h(\vec{x}') \rangle = h^2 \delta(\vec{x} - \vec{x}')$$

then one has

$$\chi(\vec{x} - \vec{y}, t, s) = h^{-2}\langle \phi(\vec{x}, t) \rangle_h h(\vec{y}).$$  \hspace{1cm} (43)

Namely, ZFC is the correlation at the time $t$ of the order parameter with the random external field.

Going to the three processes considered above, and restricting attention from now on, for simplicity, to the case of coincident points ($\vec{r} = 0$):

1. After equilibration in the pure state has occurred and the stationary regime has been entered, the order parameter correlates with the external field via the equilibrium thermal fluctuations, the FDT is obeyed

$$\chi_{st}(\tau) = \frac{1}{T} [C_{st}(\tau = 0) - C_{st}(\tau)]$$  \hspace{1cm} (44)

and since $C_{st}(\tau)$ decays to zero for $\tau > t_{eq}$, over the same timescale $\chi_{st}(\tau)$ saturates to

$$\lim_{t \to \infty} \chi_{st}(\tau) = \chi_{eq} = \frac{1}{T} C_{eq}$$  \hspace{1cm} (45)

which is the susceptibility computed in the final equilibrium state $\rho_{\pm}[\phi(\vec{x})]$ (see figure 6).
(2) As far as ZFC is concerned, there is no difference between the relaxation to the mixed Gibbs state and the relaxation to a pure state. Hence, the FDT is satisfied and can be written in terms of either $C_{st}$ or $C_G$ since, as equation (35) shows, they differ by a constant.

(3) In the phase ordering process the system stays out of equilibrium, so it useful to write the ZFC as the sum of two contributions [27]:

$$\chi(t, s) = \chi_{st}(\tau) + \chi_{ag}(t, s)$$ \hspace{1cm} (46)

where $\chi_{st}(\tau)$ satisfies equation (44) and $\chi_{ag}(t, s)$ represents the additional out of equilibrium response. In connection with this latter contribution there are two basic questions:

(i) how does it behave with time,

(ii) what is the relation between $\chi_{ag}$ and $C_{ag}$, if any.

6.2.1. Scaling hypothesis. Since ZFC study measures the growth of correlation between the order parameter and the external field, the first question raised above addresses the problem of an out of equilibrium mechanism for this correlation, in addition to the thermal fluctuations accounting for $\chi_{st}$. The starting point for the answer is the assumption of a scaling form

$$\chi_{ag}(t, s) \sim s^{-a_{\chi}} \chi_{ag}(t/s)$$ \hspace{1cm} (47)

which is the counterpart of equation (38) for the correlation function.

The next step is to make statements on the exponent $a_{\chi}$ and on the scaling function $\chi_{ag}(x)$. There exists in the literature an estimate of $a_{\chi}$ based on simple reasoning. What makes phase ordering different from relaxation in the pure or in the Gibbs state is the existence of defects. The simplest assumption is that $\chi_{ag}(t, s)$ is proportional to the density of defects $[9,10,28]$. This implies

$$a_{\chi} = \delta$$ \hspace{1cm} (48)

where the exponent $\delta$ regulates the time dependence of the density of defects $\rho(t) \sim L(t)^{-n} \sim t^{-\delta}$, namely

$$\delta = n/z$$ \hspace{1cm} (49)

with $n = 1$ for a scalar and $n = 2$ for a vector order parameter [11].

According to this argument $a_{\chi}$ should be independent of the dimensionality. This conclusion is not corroborated by the available exact, approximate and numerical results. On the basis of exact analytical solutions for the $d = 1$ Ising model [29, 30] and for the large $N$ model [31], approximate analytical results based on the Gaussian auxiliary field (GAF) approximation [32, 33] and numerical results from simulations [33]–[37] with $d = 2, 3, 4$, we have argued that

$$a_{\chi} = \begin{cases} 
\delta \left( \frac{d - d_L}{d_U - d_L} \right) & \text{for } d < d_U \\
\delta & \text{with log corrections for } d = d_U \\
\delta & \text{for } d > d_U
\end{cases}$$ \hspace{1cm} (50)

where $d_L$ and $d_U > d_L$ depend on the system in the following way:
Fluctuation dissipation relations far from equilibrium

Table 1. Parameters entering equation (50) in various models.

|         | Ising | GAF | $N = \infty$ |
|---------|-------|-----|--------------|
| $\delta$  | $1/2$ | $1/2$ | $1$          |
| $d_L$    | $1$   | $1$ | $2$         |
| $d_\chi$ | $3$   | $2$ | $4$          |

- $d_L$ is the dimensionality where $\alpha_\chi = 0$. In the Ising model $d_L = 1$, while in the large $N$ model $d_L = 2$. The speculation is that in general $d_L = 1$ for systems with discrete symmetry and $d_L = 2$ for systems with continuous symmetry, therefore suggesting that $d_L$ coincides with the lower critical dimensionality of equilibrium critical phenomena, although the reasons for this identification are far from clear.

- $d_U$ is a value of the dimensionality specific to ZFC and separating $d < d_U$, where $\alpha_\chi$ depends on $d$, from $d > d_U$ where $\alpha_\chi$ is independent of dimensionality and equation (48) holds. The existence of $d_U$ is due [35] to a mechanism, i.e. the existence of a dangerous irrelevant variable, quite similar (including logarithmic corrections) to the one leading to the breaking of hyperscaling above the upper critical dimensionality in static critical phenomena. However, $d_U$ cannot be identified with the upper critical dimensionality since we have found, so far, $d_U = 3$ in the Ising model and $d_U = 4$ in the large $N$ model. In the scalar case it may be argued [36,38] that $d_U$ coincides with the dimensionality $d_R = 3$ such that interfaces do roughen for $d \leq d_R$ and do not roughen for $d > d_R$. This will be discussed in section 6.2.2. A general criterion for establishing the value of $d_U$, however, is not yet known.

The validity of equation (47) with $\alpha_\chi$ given by equation (50) has been checked, in addition to the cases where analytical results are available, with very good accuracy in the simulations of the Ising and clock model and of the time dependent Ginzburg–Landau equation [33]–[37]. The values of $\delta$, $d_L$, and $d_U$ obtained for the different systems are collected in table 1 and the behaviour of $\alpha_\chi$ as dimensionality is varied is displayed in figure 4.

6.2.2. Roughening of interfaces. Apart from the few exact solutions mentioned above there is not a general derivation of equation (50) which, at this stage, remains a phenomenological formula. For the case of a scalar order parameter, an argument has been proposed [36,38] explaining the dependence of $\alpha_\chi$ on $d$ in terms of the roughening properties of the interfaces. It is based on two simple physical ingredients: (a) the ageing response is given by the density of defects $\rho(t)$ times the response of a single defect $\chi_{ag}(t,s) = \rho(t)\chi_{ag}^*(t,s)$ and (b) each defect responds to the perturbation by optimizing its position with respect to the external field in a quasi-equilibrium way. For $d = 1$ this occurs via a displacement of the defect [33]. In higher dimensions, since defects are spatially extended, the response is produced by a deformation of the defect shape.

We develop the argument for a 2D system, the extension to arbitrary dimension being straightforward. A defect is a sharp interface separating two domains of opposite magnetization. In order to analyse $\chi_{ag}^*(t,s)$ we consider configurations with a single defect as depicted in figure 5. The corresponding integrated response function reads [33]

\[ doi:10.1088/1742-5468/2007/07/P07002 \]
Figure 4. Exponent $a_\chi$ in different coarsening systems with scalar and vector order parameter, non-conserved and conserved order parameter [11]. The continuous lines represent equation (50), while the dots are the values from simulations [35,36].

Figure 5. Configurations with a single interface at time $s$ (dashed line) and at time $t$ (continuous line).

\[
\chi_{ag}^a(t, s) = 1/(h^2 \mathcal{L}^{d-1}) \int dx dy \langle \phi(x, y) \rangle h(x, y), \]

where $\phi(x, y)$ is the order parameter field which saturates to $\pm 1$ in the bulk of domains, and $x, y$ are space coordinates. $h(x, y)$ is the external random field with expectations (41), (42), and $\mathcal{L}$ is the linear system size. The overbar and angular brackets denote averages over the random field and thermal histories, respectively. With an interface of shape $z_s(y)$ at time $s$ (figure 5), we can write

\[
\chi_{ag}^a(t, s) = -1/(h^2 \mathcal{L}^{d-1}) \int_{\{z\}} E_h P_h(\{z(y)\}, t),
\]

where $P_h(\{z(y)\}, t)$ is the probability that an interface profile $\{z(y)\}$ occurs at time $t$ and $E_h = -\int_0^\mathcal{L} dy \int_{z_s(y)}^{z(y)} dx h(x, y) \text{sign}[z(y) - z_s(y)]$ is the magnetic energy. We now introduce assumption (b) making the ansatz for the correction to the unperturbed probability $P_0(\{z(y)\}, t)$ in the form of a Boltzmann factor.
Figure 6. Schematic plot of the behaviour of the two time functions in the coarsening stage as \( t - s \) is varied keeping \( s \) fixed (upper figure), and of the resulting fluctuation dissipation plot (lower figure). The stationary parts \( C_{st}, \chi_{st} \), as discussed in sections 6.1, 6.2, saturate to their final value in times \( \tau \simeq t_{eq} \); the ageing parts \( C_{ag}, \chi_{ag} \), according to the scaling forms (38), (47), remain constant up to times \( t - s \simeq s \). The magnitude of \( \chi_{ag} \) is proportional to \( s^{-\alpha} \chi \), and decreases as \( s \) increases (shown by an arrow in the figure).

6.3. Statics from dynamics

We may now check whether, and how, the connection between statics and dynamics discussed in section 5 is realized in phase ordering systems. In the following we shall consider \( d \geq d_L \).

---

3 This argument holds also for Ising spins. Only for \( d = 3 \) do differences arise when the Ising model undergoes a roughening transition at the temperature \( T_R \) between a low \( T \) phase with flat (faceted) domain walls and a rough high \( T \) phase [41]. Hence we expect logarithmic corrections in equation (50) only for \( T > T_R \), and a pure algebraic decay for \( T < T_R \). A numerical test of this prediction would be of great interest, but very demanding from the computational point of view.
In order to search for $S(C)$ in the case of phase ordering, let us set $\vec{r} = 0$ in equation (38) and let us eliminate $t/s$ between $\hat{\chi}_{ag}$ and $C_{ag}$ obtaining

$$\chi_{ag}(t, s) \sim s^{-a\chi} \hat{\chi}_{ag}(C_{ag}). \quad (51)$$

Then, from equations (46), (44) and (51) one can write the general relation

$$\chi(t, s) = \frac{1}{T} [C_{st}(\tau = 0) - C_{st}(\tau)] + s^{-a\chi} \hat{\chi}_{ag}(C_{ag}). \quad (52)$$

Using the identity $[C_{st}(\tau = 0) - C_{st}(\tau)] = [C_{st}(\tau = 0) + M^2 - C_{st}(\tau) - M^2]$ and considering that, as shown schematically in figure 6, in the time interval where $C_{st}(\tau) \neq 0$, i.e. for short times, one can replace $C_{ag}(t/s)$ with $M^2$ or equivalently $C_{st}(\tau) + M^2 = C(t, s)$, the above equation can be rewritten as

$$\chi(t, s) = \tilde{\chi}_{st}(C) + s^{-a\chi} \hat{\chi}_{ag}(C_{ag}) \quad (53)$$

where the function $\tilde{\chi}_{st}(C)$ is defined by

$$T\tilde{\chi}_{st}(C) = \begin{cases} [C(t, t) - C(t, s)] & \text{for } M^2 \leq C \leq C(t, t) \\ [C(t, t) - M^2] & \text{for } C < M^2. \end{cases} \quad (54)$$

Therefore, from equation (53) we have that for phase ordering systems the fluctuation dissipation relation exists if $a_\chi > 0$ (i.e. for $d > d_L$) and it is given by

$$S(C) = \tilde{\chi}_{st}(C). \quad (55)$$

Computing the derivative in the left-hand side of equation (29) and using equations (55) and (54), for $d > d_L$, we find

$$-T \frac{d^2 S(C)}{dC^2} \bigg|_{C=q} = \delta(q - M^2). \quad (56)$$

Coming to statics, in replica symmetric low temperature states, as for instance in ferromagnetic systems, the overlap function is always trivial and, as anticipated in section 5, one has

$$P(q) = \frac{1}{2} [\delta(q - M^2) + \delta(q + M^2)] \quad (57)$$

with

$$\tilde{P}(q) = \tilde{P}(q) = \delta(q - M^2) \quad (58)$$

as shown in figure 1 (I) (we recall that $q_{EA} = M^2$ in this case). From equations (58) and (56), therefore, equation (29) is satisfied, and the connection between statics and dynamics holds.

For $a_\chi = 0$ a little more care is needed. Equation (53) yields $\chi(t, s) = \tilde{\chi}_{st}(C) + \hat{\chi}_{ag}(C_{ag})$. Recalling that $a_\chi = 0$ occurs at $d = d_L$, which coincides with the lower critical dimensionality, in order to have a phase ordering process a quench to $T = 0$ is required. This, in turn, implies $C_{st}(t, s) = 0$ and $C_{ag}(t, s) = C(t, s)$. Therefore, using equation (54) we have

$$S(C) = \chi^*_{eq} + \tilde{\chi}_{ag}(C) \quad (59)$$

doi:10.1088/1742-5468/2007/07/P07002
where $\chi^*_{\text{eq}} = \lim_{T \to 0} [C(0) - M^2]/T$ is the $T = 0$ equilibrium susceptibility, which vanishes for hard spins while it is different from zero for soft spins. Therefore the FDR exists also in this case. However, while for $a_\chi > 0\chi_{ag}$ eventually disappears and equation (45) holds, this is no longer true for $d = d_L$. Here $a_\chi = 0$ and, consequently, as can be seen from equation (59) $\chi_{ag}$ gives a contribution to the response which persists also in the asymptotic time region. Then equation (45) and, hence, condition (2) above equation (29) are not fulfilled. As one of the hypotheses leading to equation (29) is violated, the connection between statics and dynamics could not hold. Actually, in all the models explicitly considered in the literature [33,35,36] it turns out that at $d = d_L$, $S(C)$ is a non-trivial dynamical function unrelated to $\tilde{P}(q)$. For the sake of definiteness, let us discuss the case of the Ising model with $d = 1$ [29,30]. In order to make compatible the two requirements of having an ordered equilibrium state and a well defined linear response function, instead of taking the $T \to 0$ limit it is necessary to take the limit of an infinite ferromagnetic coupling [29]. Then, $P(q)$ and $\tilde{P}(q)$ are given by equations (57) and (58) with $M^2 = 1$ at all temperatures. On the other hand, for any $T$ one also have [29] (see figure 7)

$$T\tilde{\chi}_{ag}(C) = \frac{\sqrt{2}}{\pi} \arctan\left[\sqrt{2} \cot\left(\frac{\pi}{2} C\right)\right].$$

This gives

$$-T \frac{d^2 S(C)}{dC^2}\bigg|_{C=q} = \frac{\pi \cos(\pi q/2) \sin(\pi q/2)}{[2 - \sin(\pi q/2)]^2}.$$  

Hence, it is clear that equation (29) is not verified. The reason is that the second of the above conditions required for establishing the connection is not satisfied. In fact, from equations (53) and (60), keeping in mind that the limits $t \to \infty$ and $C \to 0$ are equivalent, we have

$$\lim_{t \to \infty} T\chi(t,s) = 1/\sqrt{2}$$

where $\chi_{ag}(C)$ is the fluctuation dissipation plot for the 1D Ising model.
which is responsible of the violation of condition (2) above equation (29), since in this case $\chi_{eq} = 0$. Interestingly, a similar behaviour is observed [42] also for the Ising model on graphs with $T_C = 0$, which, in a sense, can be regarded as being at $d_L$.

6.3.1. Role of quenched disorder at $d = d_L$. The behaviour of the exponent $a_\chi$, and its vanishing at $d_L = 1$ can be qualitatively interpreted in terms of the behaviour of the response $\chi^s_{ag}(t, s)$ associated with a single interface. For $d = 1$ it can be shown exactly [33] that $\chi^s_{ag}(t, s) \propto (t - s)^{1/2}$. Therefore, when computing the total response through $\chi_{ag}(t, s) \simeq \rho(t)\chi^s(t, s)$ the loss of interfaces described by $\rho(t)$ is exactly balanced by the increase of $\chi^s(t, s)$, which leads to a finite $\lim_{t \to \infty} \chi_{ag}(t, s)$. This in turn is responsible for the breakdown of the condition (2) above equation (29). For $d > d_L$, instead, the growth of $\chi^s(t, s)$ is not sufficient [33] to balance the decrease of $\rho(t)$. This happens because, while for $d = 1$ interfaces are Brownian walkers, free to move in order to maximize the response, for $d > 1$ this issue is contrasted with surface tension, restoring the validity of condition (2).

In this section we examine how a similar effect, namely a reduction of the response of interfaces, can be produced, also for $d = 1$, by the presence of quenched disorder.

Let us consider the case of the $d = 1$ random field Ising model (RFIM). In the presence of a quenched random field, domain walls perform random walks in a random potential of the Sinai type and the average domain size $L(t)$ behaves as the root mean square displacement of the random walker [43]. The typical potential barrier encountered by a walker after travelling a distance $l$ is of the order of $\sqrt{l}\sigma_h$ where $\sigma_h$ is the variance of the random field. Hence, there exists a characteristic length $L_g = T^2/\sigma_h$ representing the distance over which potential barriers are of the order of magnitude of thermal energy. For displacements much less than $L_g$ diffusion takes place in a flat landscape like in the pure system and $L(t) \sim t^{1/2}$. For displacements much greater than $L_g$, instead, one finds the Sinai [44] diffusion law $L(t) \sim (\ln t)^2$. The response function obeys [45] the scaling relation (figure 8)

$$T\chi_{ag}(t, s, L_g) = \tilde{\chi} \left( \frac{L(t)}{L(s)}, z \right)$$

\textbf{Figure 8.} The ZFC $\chi_{ag}(t, s)$ is plotted versus the ratio $[L(t) - L(s)]/L(s)$, for $L_g = 400, 1600$, and $z = 0.1, 9$. The solid line is the exact result for $z \to 0$. 

doi:10.1088/1742-5468/2007/07/P07002
where \( z = L(s)/L_g \). For \( z = 0 \) the form of the response function for the pure system is recovered. With \( z > 0 \) there is a crossover. The pure case behaviour holds for \( L(t) - L(s) \ll L_g \), while for \( L(t) - L(s) > L_g \) the response levels off and then decreases. This is clearly displayed also in the plot (figure 9) against the autocorrelation function. Looking at the effective response of a single interface \( \chi_s(t, s) \) one finds \( \chi_s(t, s, L_g) = L(s)\tilde{\chi}(L(t)/L(s), z) \) with the scaling function displaying the behaviour

\[
\tilde{\chi}(x, z) \sim \begin{cases} 
  x\tilde{\chi}(x, z = 0), & \text{for } x - 1 \ll 1/z \\
  \sqrt{x}, & \text{for } x - 1 \gg 1/z.
\end{cases}
\]  

(64)

From this follows \( \chi_s(t, s) \geq \rho^{-1}_f(t) \) in the preasymptotic regime and \( \chi_s(t, s) \sim \rho^{-1/2}_f(t) \) in the asymptotic regime, which account for the crossover of the response function in figures 8 and 9 in terms of the balance between the rate of growth of the single-interface response and the rate of loss of interfaces. Hence, for \( z > 0 \) eventually \( \tilde{\chi}(x, z) \) vanishes and in the limit \( z \to \infty \) one expects \( \chi_{ag}(x, z = \infty) \equiv 0 \). Therefore, for any finite quenched random field the validity of equation (29) is restored.

6.3.2. Failure by stochastic instability. An interesting example [46], where statics cannot be reconstructed from dynamics because the third requirement of stochastic stability is not satisfied, comes from the spherical model. More precisely, one must consider in parallel the original version of the spherical model (SM) of Berlin and Kac [47] and the mean spherical model (MSM) introduced by Lewis and Wannier [48], with the spherical constraint treated in the mean. These two models are equivalent above but not below \( T_C \) [49]. The low temperature states are quite different, with a bimodal order parameter probability distribution in the SM case and a Gaussian distribution centred in the origin in the MSM case. The corresponding overlap functions are also very different [46]. Considering, for
Fluctuation dissipation relations far from equilibrium

Figure 10. Overlap distribution for the mean spherical model with $M^2 = 1$. The arrows represent the $\delta$ functions of the overlap distribution for the spherical model.

simplicity, $T = 0$ one has

$$P(q) = \begin{cases} \frac{1}{2} \left[ \delta(q - M^2) + \delta(q + M^2) \right] & \text{for SM} \\ \frac{1}{\pi M^2} K_0(|q|/M^2) & \text{for MSM} \end{cases}$$

where $K_0$ is a Bessel function of imaginary argument (figure 10).

However, after switching of an external field, one finds for both models $\tilde{P}(q) = \delta(q - M^2)$. This means that stochastic stability holds for SM but not for MSM.

On the other hand, the relaxation properties are the same in the two models, both above and below $T_C$ if the thermodynamic limit is taken before the $t \to \infty$ limit [46]. Then, the linear response functions are the same for the two models and obey equation (53) with $a_x$ given by equation (50), where $\delta$, $d_L$ and $d_U$ are the same as for the large $N$ model (table 1). Hence, we have that although equation (29) is satisfied for both models, statics and dynamics are connected only in the SM case, where $\tilde{P}(q) = \hat{P}(q)$. Instead, this is not possible in the MSM case where $\tilde{P}(q) \neq \hat{P}(q)$.

7. Conclusions

In this paper we have reviewed some recent progress in the field of non-equilibrium linear response theory. A first accomplishment is the derivation of a generalization of the FDT for Markov processes which allows the computation of the response function in terms of correlation functions of the unperturbed system. This represents a great simplification particularly in numerical calculations, which are usually computationally very demanding: the generalization of the FDT allows a sensible speed and precise numerical determination of the response function can be achieved. This quantity has been deeply investigated particularly in the field of slowly relaxing systems, because its relation with the autocorrelation function represents a bridge between statics and dynamics.

Phase ordering systems can be regarded as the simplest instance of ageing systems, where the behaviour of the response function can be more easily investigated. In this context, a partial understanding has been achieved by matching the results of numerical simulations with the outcomes of solvable models and approximate theories,
showing that the scaling properties of the response function are non-trivial. In particular, equation (47) is obeyed with $a_\chi$ depending on dimensionality through the phenomenological formula (50), which is found to be consistent with all the cases considered in the literature and, for the scalar case, is supported by an argument based on the roughness properties of the interfaces. The dependence of $a_\chi$ on dimensionality is such that it vanishes at the lower critical dimension. This implies an asymptotic finite contribution of the ageing part of the response function which invalidates the connection between statics and dynamics. Phase ordering therefore offers examples where a replica symmetric low temperature state is compatible with a non-trivial FDR which, therefore, cannot be used to infer the properties of the equilibrium state.

This whole phenomenology is not adequately captured by the existing approaches to phase ordering. Theories based on the GAF method, originally introduced by Otha, Jasnow and Kawasaki [50], provide the phenomenological formula (50) but with a wrong value $d_U = 2$ [32, 33]. This discrepancy is not removed using a perturbative expansion [51] developed to improve over the GAF approximation. Next to these theories, there is much interest in the approach by Henkel et al [52], based on the conjecture that the response function transforms covariantly under the group of local scale transformations. This ansatz, however, fixes the form of the scaling function in equation (47) but not the exponent $a_\chi$ which remains a so far undetermined quantity. A first-principles theory for the complete description of the behaviour of the linear response function in phase ordering systems may represent a prerequisite for understanding the behaviour of more complex systems, like glasses and spin glasses. However, despite some progress of a specific character, such a theory is currently still lacking.
