Abstract

We report the rapid accelerated thermalization of potassium ($^{39}$K) atoms loaded in a magnetic trap, in the presence of a single dipole trap beam. More than an order of magnitude reduction in the thermalization time, to less than a second, is observed with the focused off-resonant beam occupying only 0.01% of the volume of the magnetic trap. A new method for testing for thermalization of relatively hot clouds is devised. The cold atoms are loaded from a magneto-optical trap (MOT) of $^{39}$K that has gone through a compressed MOT and sub-Doppler cooling stage. The atoms are prepared in the magnetically stretched $|F = 2, m_F = 2\rangle$ state prior to loading into the hybrid trap. We also report a direct loading of $^{39}$K atoms, prepared in the state $|F = 1\rangle$, into a single beam dipole trap.

1. Introduction

Ultra-cold and quantum degenerate bosonic and fermionic gases can serve as a test bed for various quantum mechanical as well as quantum statistical phenomena. They have also been important in developing various applications and in studies in fundamental physics. A first step towards producing a degenerate gas of atoms is to load the pre-cooled atoms from a magneto-optical trap (MOT) [1] into a conservative trap like a pure magnetic trap [2–4] or an optical dipole trap [5]. In order to attain lower temperatures, evaporative cooling is performed on the cloud of atoms in the conservative trap. The dipole trap has the advantage that the atoms need not be spin polarized and can be prepared in any one of the hyperfine ground states. However, dipole traps inherently have a smaller volume in comparison with a magnetic trap. Also, effective 3D confinement is possible only with a crossed dipole trap (CDT).

The combination of a quadrupole magnetic trap and an optical dipole trap [6], however provides us with the merits of both kinds of confinement. The centre of the dipole trap (i.e. the focus of the beam) is overlapped with the centre of the quadrupole trap. To prevent atom loss and heating due to Majorana spin flips, the dipole trap is kept at a distance equal to its beam waist from the centre of the quadrupole field. The hybrid trap formed by this combination eliminates the need for a CDT as 3D confinement is provided by the combination of the off-resonance optical field and the magnetic field.

Of atoms in the alkali species, potassium is a good option for studies involving both bosons and fermions, in spite of the difficulty in reaching low temperatures in a vapour loaded MOT. Due to the closely spaced upper state hyperfine levels of $^{39}$K, the temperature attainable in a $^{39}$K MOT is larger than 1 mK, which is well above the Doppler temperature and a short molasses cooling phase is introduced to further reduce the temperature lower than 100 μK [7–9]. Loading into a magnetic trap results in an unthermalized sample with relatively high temperatures, and thermalization times are typically large, about 15–20 s [10]. Direct evaporative cooling is restricted by the fact that the scattering length is negative and thermalization is inefficient. It is possible to load the atoms into a hybrid trap and then switch off the magnetic field, leaving the atoms only in the optical dipole trap. Feshbach resonances can then be used to tune the scattering length between the atoms [11] for efficient direct evaporative cooling in the optical dipole trap, leading to a BEC [12]. $^{39}$K BEC was first obtained by...
sympathetic cooling with \(^{87}\text{Rb}\) and using Feshbach resonance to tune the interaction [13]. Recently, direct loading of \(^{39}\text{K}\) atoms into a CDT has also been reported [14]. Since Feshbach resonances are forbidden for atoms in state \(F = 2\) [15], it is essential to prepare the atoms in the state \(F = 1\) to tune the scattering length, for evaporative cooling to degeneracy.

In this paper we report two results of importance in this context for obtaining quantum degenerate samples: (a) optical potential assisted rapid thermalization in a magnetic trap, resulting in more than an order of magnitude reduction in the thermalization time and (b) direct loading of cold atoms from the MOT, prepared in the state \(F = 1\), into a single beam optical dipole trap. Efficient thermalization happens in the hybrid trap in spite of the fact that the volume of the optical trap relative to the magnetic trap is only about \(10^{-4}\).

For the thermalization experiments, we follow a method similar to [12] while loading \(^{39}\text{K}\). The cold atoms obtained from the MOT after sub-Doppler cooling are first prepared in the state \((F, m_F) = (2, 2)\). The atoms are then transferred to a quadrupole trap after all the MOT beams are switched off. An optical dipole beam (1080 nm, 20–50 W) with its centre overlapped with the centre of the quadrupole field is also switched on. In this way we can transfer almost 80\% of the MOT atoms into the hybrid trap.

In order to directly load \(^{39}\text{K}\) atoms from the MOT to a single beam dipole trap in the \(F = 1\) state after the sub-Doppler cooling stage, the dipole trap beam is switched on after the MOT beams and magnetic field are switched off, after a short phase of optical pumping into the \(F = 1\) state with only the cooling beam on and the repumper off. About \(10^7\) atoms are captured in the single beam dipole trap.

### Table 1. Values of various parameters during the C-MOT stage.

2. **Experiment**

2.1. **Magneto optical trap**

The vacuum assembly of the set up is described in [8]. Water cooled coils are used to create the inhomogeneous magnetic field required for the MOT and later the quadrupole magnetic trap. The atoms in the 3D MOT are loaded from a 2D+ MOT [16]. Due to the small level spacing in the hyperfine structure of \(^{39}\text{K}\), both the cooling \((F = 2 \rightarrow F' = 3)\) and repump \((F = 1 \rightarrow F' = 2)\) beams are detuned below the entire excited state hyperfine levels. As shown in [17], the cooling efficiency is different for a different combination of intensity and detuning. For loading the MOT, both the cooling and repump beams are red detuned with respect to the entire hyperfine structure of the excited states and the intensity is kept high. This helps in capturing a large number of atoms in the MOT but the cooling is ineffective. The temperature attained is \(\geq 1\) mK. If the cooling and repump beams are slightly red detuned only with respect to the respective hyperfine resonances and the intensity is kept small, the cooling is efficient but fewer atoms are captured. Thus, a two stage cooling strategy is adopted in order to trap a large number of atoms at a lower temperature. First, the MOT is prepared with beams of high intensity and detuning. To cool the atoms further a sub-Doppler stage is introduced, where both the intensity and the detuning is decreased [8, 9]. Temperatures of the order of 25–30 \(\mu\)K have been reported.

Prior to transferring the atoms into the magnetic trap, the atoms are first compressed using a combination of increased magnetic field gradient as well as a change of the detuning and intensity of the laser beams. This stage is called the compressed MOT (C-MOT) stage (see table 1).

After the C-MOT stage, a molasses cooling stage is implemented in which we change the intensity and detuning of both the cooling and repump beams. The values of the intensity and detuning during the sub-Doppler cooling stage are shown in table 2.

Temperature of the order of 70 \(\mu\)K is achieved after the two stages described above.

2.2. **Loading into a magnetic trap**

In order to load the atoms into the quadrupole magnetic trap, the atoms have to be prepared in the magnetically stretched \(|F = 2, m_F = 2\rangle\) state, by shining a circularly polarized light beam slightly blue detuned to the transition \(F = 2 \rightarrow F' = 2\) on the atoms in the MOT. A magnetic field of around 5 Gauss is also switched on. To prevent optical pumping to the hyperfine level \(F = 1\) we also mix a beam resonant with the repump transition along with the spin polarizing beam. In order to avoid heating during the spin polarization process, we keep the state preparation beams on for a short duration of about 100 \(\mu\)s only.

This is essential for the loading of atoms into the magnetic trap as long duration pulses reduce the efficiency with which the atoms are captured in the trap. The quadrupole magnetic field is switched on immediately after preparation of the atomic cloud in the desired state. It takes about 10 ms to reach the final magnetic field gradient of about 95 Gauss cm\(^{-1}\) in the plane perpendicular to the coil axis (190 Gauss cm\(^{-1}\) along the coil axis). Loading efficiency of about 80\% has been observed. The atoms in the magnetic trap are imaged via absorption imaging in the 2f–2f configuration, using an absorption probe resonant to the cooling transition \((F = 2 \rightarrow F' = 3)\).

2.3. **Hybrid and dipole traps**

The hybrid trap is created by aligning the dipole trap centre (the focus of the dipole trap beam) with the centre of the
quadrupole trap. The dipole trap is derived from a 1080 nm ($\Delta \lambda \sim 1$ nm) unpolarized fibre laser (Manlight, France).

The dipole beam has a beam waist of 25 $\mu$m at the focus and a Rayleigh length of about 1800 $\mu$m, which exceeds the magnetic trap size. At a maximum power of 50 W, the trap depth of the dipole trap is around 1.9 mK. The dipole trap beam is switched on together with the magnetic trap. The effective potential of the hybrid trap is given by [6]:

$$ U(\vec{r}) = \mu B' (x^2/4 + y^2/4) + U_0 \exp \left( -2(y^2 + z^2)/w_0^2 \right) + mgy $$

where $\mu$, $B'$, $U_0$ and $g$ are the magnetic dipole moment of the atom, magnetic field gradient, dipole trap depth and the acceleration due to gravity, respectively. The dipole trap is along the $x$-axis. Here, we are considering the case where the focus of the dipole trap beam coincides with the centre of the magnetic trap. The typical dipole trap depth and magnetic field gradient used in our experiment are $U_0 = 1.9$ mK and $B' = 190$ Gauss cm$^{-1}$.

3. Results

3.1. Thermal relaxation in the hybrid trap

The transfer of atoms from the MOT to the magnetic trap leads to an unequal distribution of energy (temperature) and hence expansion velocities along different directions. This anisotropy and its time evolution can be measured from the rates of expansion of the atomic cloud along different directions, after releasing the atoms from the trap. During free expansion, the size of the cloud increases with time releasing the atoms from the trap. During free expansion, the expansion of the atomic cloud along different directions, after and its time evolution can be measured from the rates of transfer of atoms from the MOT to the magnetic trap leads to an unequal distribution of energy (temperature) and hence a function of duration of expansion, for both cases, is plotted in figure 1. The clear difference in the aspect ratios in the two cases allows us to use this as a test for thermalization.

A standard way to observe thermal relaxation would be to allow for a long expansion duration after which the aspect ratio for a thermally relaxed cloud would approach unity as the expanded cloud size will become independent of the initial cloud size. This is feasible for samples with temperatures well below 100 $\mu$K and initial size occupying a small fraction of the field of view. However for samples with temperatures well above the Doppler temperature, the thermal expansion is too fast for this technique to be reliable. Hence we have devised a new technique to test for thermalization with relatively small duration of expansion.

To measure the thermalization time, we let the cloud expand after varying amounts of holding time in the trap. After a long expansion time, a thermally relaxed cloud attains an aspect ratio of 1 asymptotically. For a non-thermal cloud, the aspect ratio crosses unity during the expansion because the expansion rate is different along different directions (figure 1). Typically the temperature and the expansion rate in the direction of tighter trapping is larger. This implies that for a thermally relaxed cloud expanding for a fixed amount of time, the aspect ratio should be independent of the holding time in the trap once the holding time exceeds the thermalization time. If the holding time is lower than the relaxation time, the expansion rate in the two directions will remain different.

We measure the aspect ratio of the cloud after allowing for 4 ms of expansion for various holding times. It is observed that beyond a certain holding time $\tau_c$, in the hybrid trap, the aspect ratio becomes nearly independent of the holding time (see figure 2). We call the time required to approach 90% of

![Figure 1](https://via.placeholder.com/150)

**Figure 1.** The aspect ratio $W_i/W_x$ of the atomic cloud for various expansion times after releasing from the quadrupole magnetic trap and hybrid trap with a holding time of 2 s. $W_x$ and $W_y$ are the cloud size along the x- and y-axis respectively.

![Figure 2](https://via.placeholder.com/150)

**Figure 2.** (a) Thermal relaxation in a hybrid trap, (b), (c) and (d) shows the thermal relaxation in magnetic trap after the dipole trap has been kept on for 1 s, 500 ms and 200 ms respectively, (e) shows the thermal relaxation in the magnetic quadrupole trap only.
the final aspect ratio, with anisotropy in temperature less than 5%, as the thermal relaxation time $\tau_c$ in the hybrid trap.

From figure 2 we can see that the thermal relaxation in the case of the hybrid trap is an order of magnitude faster than that of the quadrupole trap. In order to confirm that the accelerated thermal relaxation is solely due to the presence of the dipole trap beam, we keep the beam on for 1 s, 500 ms and 200 ms and allow the cloud to relax in the magnetic quadrupole trap only. We see that the cloud continues to relax at a slower pace (as in the case of the magnetic trap) once the dipole trap is switched off. We measure the thermal relaxation time in the hybrid trap to be about $\sim 0.7 \pm 0.09 \, \text{s}$.

The relaxation time in the pure magnetic trap is too long to be measured accurately. We can see only the linear part of the slow thermal relaxation in the case of the magnetic trap in figure 2. The thermal relaxation has been obtained approximately by fitting it to a linear function and is found to be more than 20 s, consistent with previously reported long relaxation times in a quadrupole magnetic trap of more than 10 s [10]. Theoretical calculation of the scattering length [18] suggests that the Ramsauer minimum is around 400 $\mu$K. However, experimental studies of the scattering length variation with temperature are very few and the measured numbers differ from the calculated values. This calls for a more careful experimental determination of the Ramsauer minimum.

The physical mechanism for relaxation towards thermal equilibrium is collisions. Atoms need to undergo a sufficient number of collisions in the hybrid trap to redistribute the energy equally among the motional degrees of freedom in different directions and become thermally relaxed. The relaxation time for thermal equilibrium is of the order of $3\gamma^{-1}$ [19, 20] where $\gamma$ is the collision rate per atom. However, the dipole trap beam occupies only about 0.01% of the total hybrid trap volume and yet, essentially all the atoms in the hybrid trap become thermally relaxed. Therefore, thermalization should happen during the multiple crossing passages of the atoms in the magnetic trap through the single dipole beam that spans the entire length of the weakly trapping direction of the hybrid trap. The fact that atoms spend only a small fraction of time (less than 1/10 of the 700 ms we measure) within the dipole beam regions accentuates the dramatic reduction in the relaxation time in the presence of the dipole beam.

The typical collision rates can be estimated from the approximately measured atom number densities in different regions of the hybrid trap. We estimate the average atomic density ($\langle n \rangle$) of the atoms in the dipole trap region, $\langle n_{\text{dipole}} \rangle \approx 90 \times n_{\text{magnetic}}$ (density in magnetic trap). This induces a collision rate ($\gamma_c$) of 48/s at the dipole trap region compared to 0.5/s in the magnetic trap. Thus almost all of the collisions required for thermal relaxation occur in the dipole trap region. We estimate that within the measured thermal relaxation time $\tau_c \approx 700 \, \text{ms}$ the atoms spend less than 40 ms on average inside the dipole trap. This time is evaluated for our magnetic trap oscillation frequency of 200 Hz and for velocity of the atoms $\approx 0.56 \, \text{m/s}$ (for 500 $\mu$K atomic cloud). Thus each atom undergoes at most two collisions during the time it spends in the dipole trap. However, the maximum velocity of the atoms is almost a factor of 3 larger as the atom traverses the 1.9 mK deep optical potential well, and the effective collision rate is expected to be proportionately higher. This is marginally consistent with the number of collisions required for complete thermalization, which is about five collisions [21]. The small discrepancy might be due to an underestimation of the atomic density in the optical dipole trap region. In any case, the vastly accelerated thermalization becomes very useful for performing RF evaporation in the hybrid trap to get ultra-cold atomic samples.

For a fixed holding time, the thermal relaxation will depend on the power in the dipole trap. We hold the atoms in the hybrid trap for about 2 s and allow the cloud to expand for 1.5 ms before we take the image. The aspect ratio of the cloud is measured for different values of the dipole trap power. From figure 3 we can see that the aspect ratio starts becoming steady at higher power. This is because thermalization takes place within the holding time and the aspect ratio of the cloud in the trap is maintained. The absorption images of the magnetic trap and the hybrid trap, after a holding time of 2 s, are seen in figures 4(a) and (b), respectively. It must be noted that the ellipticity of the cloud is due to the anisotropy of the magnetic quadrupole trap whose gradient is stronger along the axis of the
3.2. Loading of atoms into the single beam dipole trap

To load the atoms into the single beam dipole trap, directly from the MOT, the atoms are prepared in the $F = 1$ state by letting the cooling beam remain on for 1 ms after the sub-Doppler cooling stage while the repump beam is switched off. The dipole trap beam is then switched on and atoms are held in the dipole trap for about 50 ms after which we take an absorption image of the trapped cloud. The dipole beam has a beam waist of 25 μm at the focus and a Rayleigh length of about 1800 μm. Figure 5(a) shows the absorption images of a single beam dipole trap of $^{39}$K. The number of atoms loaded into the single beam dipole trap is measured as a function of the dipole trap beam power. From figure 5(b), we see that the number of trapped atoms increases with increasing power. This is different from the situation observed in direct loading into a CDT [14]. Temperature of the atoms in the dipole trap is measured to be 250 ± 9 μK.

4. Summary

Accelerated thermalization by about a factor of 30 has been observed in a cloud of trapped $^{39}$K atoms. This increase is assisted by the presence of a steep 1D optical potential spanning almost the entire diameter of the magnetic trap, whose volume is smaller by a factor of $10^{-4}$ compared to the volume of the magnetic trap. Faster RF evaporative cooling of potassium as well as other species can thus be performed in such a trap. Direct loading of the $^{39}$K from a MOT into a single beam dipole trap has also been observed. Prior to loading, the atoms are prepared in the $F = 1$ hyperfine state which is conducive for Feshbach resonances. A CDT will be implemented and Feshbach resonances will be used on the trapped atoms to tune their interaction for efficient evaporation to quantum degeneracy in the dipole trap.
