Abstract
The natural regrowth of *Axonopus aureus* in native pasture of Roraima’s savannas was evaluated, during early rainy period. The experimental design was a completely randomized, with four replications. The treatments consisted of four pasture rest periods (14, 28, 42 and 56 days after beginning of the rainy period). Evaluations were carry out during the period of June to August of 2016. The parameters measured were dry matter (DM) yields and grass morphogenetic and structural characteristics. The green and total DM, number of tillers plant\(^1\), number of axillary tillers plant\(^1\), number of live tillers plant\(^1\), number of live leaves tiller\(^1\) and leaf area index were directly proportional to rest periods. The leaf appearance and elongation rate were negatively affect by rest periods, while the dead DM was not affect by rest periods. Considering the low green DM availability of *A. aureus*, its recommends the utilization of some management practice, preferentially grazing or mowing, to remove the dead DM with low nutrition value and permit a grass vigorous regrowth in the beginning of the rainy period.

**Keyword:** Dry matter; Leaves; Morphogenesis.

Resumo
Avaliou-se a rebrota natural de *Axonopus aureus* em pastagens nativas dos cerrados de Roraima, no início do período chuvoso. Os tratamentos consistiram de quatro períodos de descanso (14, 28, 42 e 56 dias decorridos o início do período chuvoso). O delineamento experimental foi inteiramente casualizado com quatro repetições. As avaliações foram realizadas no período de junho a agosto de 2016. Os parâmetros mensurados foram rendimento de forragem e características morfogênicas e estruturais da gramínea. Os rendimentos de matéria seca verde e total, número total de perfilhos planta\(^1\), número de perfilhos axilares, número de perfilhos vivos e índice de área foliar foram diretamente proporcionais aos períodos de descanso, ocorrendo o inverso quanto à taxa de aparecimento e de expansão de folhas, enquanto que os rendimentos de matéria seca morta não foram afetados. Considerando-se a baixa disponibilidade de matéria seca verde de *A. aureus*, recomenda-se a utilização de alguma prática de manejo, preferencialmente o pastorejo ou a roçagem, de modo a remover o material morto e de baixo valor nutritivo e permitir uma rebrota mais vigorosa da gramínea no início do período chuvoso.

Palavras-chave: Matéria seca; Folhas; Morfogênese.

Resumen
Se evaluó el rebrote natural de *Axonopus aureus* en pastizales nativos en las sabanas de Roraima, al comienzo de la temporada de lluvias. Los tratamientos consistieron en períodos de descanso (14, 28, 42 y 56 días después del comienzo de la temporada de lluvias). El diseño experimental fue completamente al azar con cuatro repeticiones. Las evaluaciones se realizaron de junio a agosto de 2016. Los parámetros medidos fueron el rendimiento de forraje y las características morfogénicas y estructurales de la gramínea. Los rendimientos de materia seca verde y total, número total de macollas planta\(^1\), número de macollas axilares, número de macollas vivas e índice de área foliar fueron directamente proporcionales a los períodos de descanso, ocurriendo lo opuesto en cuanto a las tasas de aparición y expansión de las hojas, mientras que los rendimientos de materia seca muerta no se vieron afectados. Considerando la baja disponibilidad de materia seca verde de *A. aureus*, se recomienda utilizar alguna práctica de manejo,
preferiblemente pastoreo o siega, con el fin de remover material muerto y de bajo valor nutricional y permitir más rebrote al comienzo de la temporada de lluvias.

**Palabras clave:** Materia seca; Hojas; Morfogénesis.

### 1. Introducción

Los pastizales nativos de las granjas de Roraima, a pesar de las limitaciones cuantitativas y cualitativas, han proporcionado soporte alimenticio para la explotación ganadera, que ha sido, a lo largo de los años, la actividad económica principal en la región (Costa et al., 2008). El sistema de pastoreo continuo con tasa de pastoreo variable, pero en general extensivo y superextensivo y desvinculado del ritmo produccional, ha tenido una contribución directa a los bajos índices productivos de las ganaderías. Como forma de mejorar las condiciones de alimentación, los criadores utilizan el fuego, una práctica de manejo de pastizales propuesto para eliminar la materia no consumida y endurecida, provocando un mejoramiento en la calidad nutricional cuando en estadios tempranos de crecimiento, donde la hierba se vuelve más tierna (Braga, 1998). En los pastizales nativos de las granjas, donde la hierba *Axonopus aureus* representa entre el 30% y el 45% de su composición botánica, la producción animal puede ser muy baja, lo que hace que la actividad ganadera sea económicamente ineficaz en áreas donde es su predominio, si no se implementan prácticas para su mejoramiento (Gianluppi et al., 2001).

En los años, el fuego ha sido el único elemento de manejo y el gran seleccionador de las especies nativas de pastizal en este ecosistema, siendo utilizado hasta tres veces al año, constituyendo un factor ecológico importante en la región, pero con altas consecuencias y efectos negativos en la conservación de las condiciones ambientales derivadas de actividades ganaderas (Braga, 1998; Costa et al., 2008). Los estudios realizados con diferentes tipos de pastizales nativos en regiones tropicales han demostrado los efectos perniciosos del fuego en las propiedades físicas y químicas del suelo, además de propiciar incrementos efímeros y de baja magnitud en el rendimiento y calidad de la pasto. A pesar de ser ecosistemas relativamente estables, los pastizales, gestionados con el fuego, no permiten obtener indicadores técnicos y de ambiente que garanticen su sostenibilidad económica, lo que implica una explotación ganadera obsoleta con escasas perspectivas para el futuro (Costa et al., 2013). En consecuencia, el uso de prácticas alternativas al uso del fuego emerge como herramientas de manejo que pueden moderar y mejorar los sistemas tradicionales de explotación ganadera en la región. Así, el conocimiento de las características morfoestructurales proporciona una visión de la producción forrajera y una estimación de su calidad (Pereira, 2013), además de permitir la propuesta de prácticas de manejo específicas para cada tipo de hierba forrajera (Lemaire et al., 2011; Tesk et al., 2020).

En este trabajo se evaluaron el rendimiento forrajero y las características estructurales y morfoestructurales de los pastizales regenerativos de *Axonopus aureus* en diferentes períodos de reposo, en el comienzo de la temporada de lluvias.

### 2. Metodología

El estudio fue un ensayo de campo, realizado en condiciones naturales y utilizando el método cuantitativo. Dado que aún existen brechas en torno a los efectos de los diferentes periodos de defoliación en el rendimiento productivo de pastizales forrajeros tropicales, se decidió utilizar la metodología hipotético-deductiva (Pereira et al., 2018).

El ensayo se realizó en el campo experimental de Embrapa Roraima, ubicado en Boa Vista (60°43'51" Oeste longitud y 2°45'25" Norte latitud), desde junio a agosto de 2016, que correspondió a un acumulado de precipitación de 1,416 mm y una temperatura promedio mensual de 24.79ºC. El clima de la región, según la clasificación de Köppen, es Aw, caracterizado por periodos definidos de lluvias y secas de aproximadamente seis meses cada uno. El año de lluvias es de 1,600 mm, con 80% ocurriendo en el periodo de abril a septiembre. El suelo del área experimental es un Latoso amarelo, textura media, con las siguientes características químicas, a una profundidad de 0-20 cm: pHH2O = 4.8; Ca = 0.25 cmol.c/dm³; Mg = 0.65 cmol.c/dm³; K =
0.01 cmolc.dm⁻³; Al = 0.61 cmolc.dm⁻³; H+Al = 2.64 cmolc.dm⁻³; SB = 0.91 cmolc.dm⁻³; Cation Exchange Capacity = 3.6 cmolc.dm⁻³; V(%) = 25.6 and m(%) = 40.

The experimental design was complete randomized with four replications. The treatments consisting of four rest periods (14, 28, 42 and 56 days after the beginning of the rainy season). Each experimental unit was represented by a plot with 2.0 m², with a useful area of 1.0 m². The evaluations were carried out in a pasture that was not subjected to physical (burning), mechanical (mowing) or biological (grazing) methods for lowering at the end of the dry period.

The parameters evaluated were dead dry matter yield (DDM), green dry matter (GDM), total dry matter (TDM), plant tiller number (PTN), axillary tillers number (ATN), live tillers number (LTN), live leaf tiller⁻¹ number (LLN), leaf area index (LAI), leaf appearance rate (LAR) and leaf expansion rate (LER). With the exception of DM yields that were determined throughout the useful area of the plot, for the other variables, the evaluations were carried out in four tussock plot⁻¹, selected according to their heights and diameters, in order to represent the variability of the population of plants in each plot. LAR, LER and LAI were determined only in live tillers. LAR and LER were calculated by dividing the accumulated leaf length and the total number of leaves in the tiller, respectively, by the regrowth period.

To calculate the leaf area, samples of completely expanded green leaves were collected, trying to obtain an area between 200 and 300 cm². The samples were digitalized and the leaf area estimated with the aid of an electronic optical Planimeter (Li-Cor 3100C). Subsequently, the sample was taken to the greenhouse with forced air at 65°C until they reached constant weight, obtaining the leaf GDM. Specific leaf area (SLA) was determined by the relationship between green leaf area and its GDM (m²/g leaf GDM). The LAI was determined from the product of the total green leaf GDM (g GDM/m²) by SLA (m²/g leaf GDM).

The data were subject to analysis of variance and regression considering the significance level of 5% probability. In order to estimate the response of the parameters evaluated to the rest periods, the choice of regression models was based on the significance of the linear and quadratic coefficients, using the Student's “t” test, at the level of 5% probability.

3. Results and Discussion

The DGM yields were not affected (P>0.05) by rest periods, with average forage availability of 2,341 kg/ha. The GDM and TDM were positively and linearly increase with larger rest period (Table 1). These values are lower than those reported by Heringer and Jacques (2002) for native pastures in Rio Grande do Sul managed in the absence of fire or clearing (3,025 kg/ha). However, in both situations, the availability of forage, despite being satisfactory in quantitative terms, is characterized by low nutritional value as consequence of the high proportion of senescent leaves and would hardly be consumed by the animals, given its high levels of fiber and low concentration of nutrients. Most native grasses in the Roraima’s savannas have high retention of senescent leaves, which can negatively affect nutrient recycling processes, making it necessary to use some management practice, preferably grazing or mowing, in order to favor a fast and vigorous regrowth, consisting of forage with high nutritional value and great acceptability by the animals.
Senescence is the natural process that characterizes the last phase of leaf development. It’s start after its complete expansion and progressively accentuated with the increase in leaf area, due to the shading of the leaves inserted in the lower portion and the low supply of photosynthetically active radiation, in addition to strong competition for light, nutrients and water between the different strata of the plant (Nabinger & Pontes, 2002). When tiller reach a certain number of live leaves, there is a balance between the rate and appearance and the senescence of leaves that have exceed their life span. So that the appearance of a new leaf implies in the senescence of the leaf that preceded it, so that the number of live leaves is relatively constant (Lemaire et al., 2011).

Despite the negative effect on forage quality, senescence represents an important physiological process in grass tissue flow, as about 50% of the carbon and 80% of the nitrogen can be recycled from senescent leaves and used by the plant for the production of new leaf tissues (Carrère et al., 1997; Lemaire & Agnusdei, 2000; Tesk et al., 2020). Senescence negatively affects forage quality, however it represents an important physiological process in grass tissue flow, as around 35; 68; 86 and 42% of nitrogen, phosphorus, potassium and magnesium, respectively, can be recycled from senescent leaves and used to produce new leaf tissue (Sarmiento et al., 2006; Costa et al., 2013).

Considering an available use efficiency forage of 50% and an average daily intake of 11.25 kg of GDM AU-1 (AU = 450 kg of live weight), which represents 2.5% of the animal’s live weight (Costa, 2014; Costa et al., 2021). So the availability of GDM record in this work would provide grazing periods of 20.2; 32.1; 38.1 and 46.2 days, respectively for rest periods of 14, 28, 42 and 56 days. Thus, as long as no pasture management practices are adopt, it is recommend start grazing 56 days after the beginning of the rainy season. Mochiutti et al. (2009), evaluating forage availability from native pastures in the Amapá’s savannas, submitted to annual, biennial or clearing burning, estimated yields of 1,302; 1,493 and 1,353 kg/ha of TDM, respectively, which were lower than those obtained in this work.

The plant tiller number (PTN), live tillers number (LTN) and the live leaf number (LLN) were fitted to the quadratic regression model, with the maximum values estimated at 41.1; 50.8 and 43.2 days, while the axillary tillers number (ATN) was directly proportional to the rest periods (Table 1). The correlation between LTN and GDM yield was positive and significant ($r = 0.9497$; $P=0.0057$), which explained in 90.2% the increases observed in grass forage yield, as a function of rest periods. In percentage terms, the participation of LTN represented only 30.9; 33.4; 33.8 and 29.7% of PTN, respectively for plants at 14, 28, 42 and 56 days of regrowth, which significantly contributes to the low GDM availability. The low ATN shows that there was no removal of the apical meristems, being grazing or mowing the most recommended practice, so that the predominance of basilar tillers over the axillary ones was not suppress (Costa et al., 2013; Souza, 2018; Silveira, 2020).

The leaf appearance rate (LAR) and leaf area index (LAI) were directly proportional to rest periods, while the leaf elongation rate (LER) was adjust to the quadratic regression model and the maximum value obtained at 50.2 days (Table 2).
The values of this work, in all rest periods, were lower than those reported by Costa et al. (2008), evaluating *Axonopus aureus*, under different grazing frequencies, who estimated mean values of 0.101 leaves tiller\(^{-1}\) day\(^{-1}\); 2.11 cm day\(^{-1}\) tiller\(^{-1}\) and 0.59 m\(^2\) m\(^{-2}\), for plants at 45 days of regrowth. Cruz et al. (2021) reported an inverse relationship between appearance and expansion of leaves, as the greater the speed of appearance of leaves, the shorter the period available for their expansion. The LER has a high correlation with GDM grass production and has been used as a criterion for grass selection in genetic improvement works, as it is directly related to the final leaf length, as smaller leaves are usually associated with higher LAR values (Nabinger & Carvalho, 2009; Pereira, 2013; Martuscello et al., 2019; Costa et al., 2021).

**Table 2.** Leaf appearance rate (LAR), leaf expansion rate (LER) and leaf area index (LAI) of *Axonopus aureus*, as affected by rest periods.

| Variables                      | Rest Periods (days) | Regression Equation             |
|--------------------------------|---------------------|---------------------------------|
|                                | 14                  | 28                              | 42                              | 56                              |
| LAR (leaf day\(^{-1}\) tiller\(^{-1}\)) | 0.157               | 0.175                           | 0.138                           | 0.091                           | \(Y = 0.199 - 0.0017 \times X (r^2 = 0.92)\) |
| LER (cm day\(^{-1}\) tiller\(^{-1}\))  | 2.07                | 2.73                            | 3.15                            | 3.22                            | \(Y = 1.08 + 0.0803 \times X - 0.0008 \times X^2 (r^2 = 0.91)\) |
| LAI (m\(^2\)/m\(^2\))            | 0.68                | 1.11                            | 1.45                            | 1.58                            | \(Y = 0.445 + 0.0217 \times X (r^2 = 0.95)\) |

Source: Research data.

4. Conclusion

The green and total dry matter yields, tiller number, axillary tiller number, leaf area index, live tiller and leaf number was positive affected by rest periods. However, the opposite was observe for leaf appearance and elongation rates, while dead dry matter yields were not affected by rest periods.

Considering the low availability of green dry matter from *Axonopus aureus*, it is recommended to use some pasture management practice, preferably grazing, in order to remove dead material and of low nutritional value to allow a more vigorous regrowth of the grass at the beginning of the rainy season.
