ABSTRACT

We have undertaken a spectral-line imaging survey of a 6 × 6 arcmin2 area around Sgr B2 near the centre of the Galaxy, in the range from 30 to 50 GHz, using the Mopra telescope. The spatial resolution varies from 1.0 to 1.4 arcmin and the spectral resolution from 1.6 to 2.7 km s−1 over the frequency range. We present velocity-integrated emission images for 47 lines: 38 molecular lines and 9 radio recombination lines.

There are significant differences between the distributions of different molecules, in part due to spatial differences in chemical abundance across the complex. For example, HNCO and HOCO+ are found preferentially in the north cloud, and CH2NH near Sgr B2 (N). Some of the differences between lines are due to excitation differences, as shown by the 36.17 and 44.07 GHz lines of CH3OH, which have maser emission, compared to the 48.37 GHz line of CH3OH. Other major differences in integrated molecular line distribution are due to absorption of the 7-mm free-free continuum emission (spatially traced by the radio recombination line emission) by cool intervening molecular material, causing a central dip in the molecular line distributions.

These line distribution similarities and differences have been statistically described by principal component analysis (PCA), and interpreted in terms of simple Sgr B2 physical components of the cooler, lower density envelope, and dense, hot cores Sgr B2 (N), (M) and (S).

Key words: ISM:individual (Sagittarius B2) – ISM:molecules – radio lines:ISM – ISM:kinematics and dynamics.

1 INTRODUCTION

Sagittarius B2 (Sgr B2) is a giant molecular cloud complex near the centre of the Galaxy. There is spectacular star-formation activity, much of it deeply embedded in molecular cores, as traced by the high far-infrared luminosity, compact and ultracompact H II regions (Gaume et al. 1995), with maser emission from water (McGrath, Goss & De Pree 2004), hydroxyl (Gaume & Claussen 1990), formaldehyde (Mehringer et al. 1994) and methanol, both class I and class II (Caswell 1996; Mehringer & Menten 1997).

Three major star-forming centres are located in a north-south line, labelled north, middle and south, Sgr B2 (N), (M) and (S), which have strong continuum radio H II region free-free emission, and submillimetre and millimetre wavelength thermal dust emission (Gordon et al. 1993; Pierce-Price et al. 2000). These cores are surrounded by a larger, less dense envelope.

The hot cores Sgr B2 (N) and (M) are particularly rich in molecules, and so have been the targets of many millime-
Hasegawa et al. (1994, 2008) as a cloud-cloud collision between a clump at 70 - 80 km s\(^{-1}\) and the 40 - 50 km s\(^{-1}\) cloud triggering the current star formation: the collision changes the velocity of material, leaving a deficit (the hole) in the 40 - 50 km s\(^{-1}\) range, as material shifts to the intermediate velocity of the 60 - 65 km s\(^{-1}\) range.

The spatial distribution in the Sgr B2 molecular cloud is also complex, but can be largely described by a ridge of emission in a north-south line near the Sgr B2 (N), (M) and (S) hot cores, or centred to the west of these cores (Jones et al. 2008a). This ridge continues to a peak 1 arcmin north of Sgr B2 (N), the ‘north cloud’ which is enhanced in HNCO and HOCO\(^+\) (Minh et al. 1998), possibly associated with the shock of the cloud-cloud collision. This ridge of emission coincides with the Sgr B2 extended envelope, as traced by sub-mm dust emission (Pierce-Price et al. 2000).

In this paper, we present results of imaging the Sgr B2 region (6 \times 6 arcmin\(^2\)) in multiple spectral lines, over 30 to 50 GHz (the 7-mm band), using the Mopra telescope. This follows on a similar spectral-line imaging survey of Sgr B2 in the 3-mm band, presented as Jones et al. (2008a), Jones, Burton & Cunningham (2008b) and Jones, Burton & Lowe (2008c). This study provides spatially resolved line distributions of a large number of molecules and transitions to constrain chemical models of the Sgr B2 complex.

2 OBSERVATIONS AND DATA REDUCTION

The observations were made with the 22-m Mopra radio telescope, of the Australia Telescope National Facility (ATNF) using the UNSW-MOPS digital filterbank. The Mopra MMIC receiver has a bandwidth of 8 GHz, and the MOPS backend can cover the full 8-GHz range in the broad band mode. This gives four 2.2-GHz sub-bands each with 8192 channels of 0.27 MHz. There is also a zoom mode with up to sixteen spectra (up to four in each 2.2-GHz sub-band) of width 137 MHz. This provides higher spectral resolution with 4096 channels of 0.033 MHz in each zoom spectrum. We chose the broad band mode, as the lines in Sgr B2 are wide, so that the 0.27 MHz channels, corresponding to around 1.6 to 2.7 km s\(^{-1}\), are quite adequate to resolve their structure. This mode also allowed a complete line-mapping survey to be made, without pre-selecting which lines would be covered, or the restrictions of selecting at most four lines in each 2.2 GHz sub-band.

The Mopra receiver covers the range 30 to 50 GHz in the so-called 7-mm band, so the band actually covers wavelengths 6 to 10 mm. We chose three tunings centred at 45.7, 38.0 and 34.1 GHz, to cover the range whole 30 to 50 GHz range. The latter two tunings overlap, with two 2.2 GHz sub-bands in common in the range 34 to 38 GHz.

The area was observed with on-the-fly (OTF) mapping, in an area 6 \times 6 arcmin\(^2\), centred near Sgr B2 (N) and (M), in a similar way to that described in Jones et al. (2008a). However, unlike the 3-mm imaging (Jones et al. 2008a), we used galactic coordinates for the scan direction, and hence the square scan area. We used position switching for bandpass calibration with the off-source reference position observed before each 6 arcmin long source scan. The system temperature was calibrated with a noise diode. The 7-mm Mopra system does not use paddle scans (unlike the 3-mm system), and hence does not correct for the absorption through the atmosphere. This effect on calibration is around the 10 percent level, so we take that as the major uncertainty in the data.

The OTF data were turned into FITS data cubes with the LIVEDATA and GRIDZILLA package\(^3\). The raw data files in RP-FITS\(^4\) format, were bandpass corrected using the off-source reference spectra with LIVEDATA, a robust second order polynomial fitted to the baseline and subtracted, and the data output as SDFITS\(^5\) (Garwood 2000) spectra. These spectra were then gridded into data cubes using GRIDZILLA, with a median filter for the interpolation. The median was used, as this is much more robust to the effect of bad data.

The whole 8-GHz band for each tuning was first turned into four cubes with frequency products for the 2.2-GHz sub-bands, making twelve cubes overall covering the entire 30 to 50 GHz range. These were used to conduct a full line survey in this spectral range. We compiled a list of the strongest (identified) lines, as given in Table 1\(^6\).

The GRIDZILLA scripts also allowed the lines (Table 1\(^6\)) to be specified, with their rest frequencies, so that the GRIDZILLA output provides FITS cubes with velocity coordinates. We used this for a second pass through the data, to produce individual cubes for each line, over a velocity range -300 to 300 km s\(^{-1}\). For the data over the frequency range 34 to 38 GHz, where two of the tunings overlapped, we combined the data from both observations to improve the signal-to-noise.

The FITS cubes were then read into the MIRIAD (Sault, Teuben & Wright 1995) package for further processing and analysis. As the emission is typically of low surface brightness, the data were smoothed in velocity, with a 3-point hanning kernel, to make data cubes with improved surface brightness sensitivity. This gives around 0.54 MHz, or 3.2 to 5.4 km s\(^{-1}\) effective FWHM spectral resolution (across the spectral range), and ensures the data are Nyquist sampled in velocity.

The resolution of the Mopra beam in the 7-mm band was recently measured by Urquhart et al. (2010) to vary between 0.99 arcmin at 49 GHz and 1.37 arcmin at 31 GHz, or roughly \(\theta \propto \lambda / D\) (where \(D\) is the 22-m dish diameter). We will assume these values to give resolution between 1.0 arcmin at 50 GHz, and 1.4 arcmin at 30 GHz, with the caveats that: a) this is somewhat smaller than previously quoted in the Mopra documentation as 82 arcsec (1.37 arcmin) at 42 GHz\(^7\); b) actually gives a somewhat flatter variation than expected from \(\theta \propto \lambda / D\). Since we are mostly concerned in this paper with the spatial and velocity structure, we have left the intensities in the \(T_A\) scale, without correction for the main beam efficiency onto the \(T_A MB\) scale. The measured main beam efficiencies \(\eta_{MB}\) vary between 43 and 53 percent within the range 31 to 49 GHz, and extended beam efficiencies \(\eta_{XLB}\) from 56 to 69 percent (Urquhart et al. 2010).

3 RESULTS

We have produced data cubes for the 47 strongest lines in the 30 to 50 GHz range, as listed in Table 1\(^6\). The flag in the last column of Table 1\(^6\) refers to the source of the line identification. Most are from the NIST database\(^2\) of lines known in the interstellar medium (Lovas & Dragoš 2004). As Sgr B2 is among the richest known sources of interstellar lines, these lines are mostly already well-known in Sgr B2. There are also some radio recombination lines,

\(^6\) http://physics.nist.gov/PhysRefData/Micro/Html/contents.html
\(^7\) http://physics.nist.gov/PhysRefData/Micro/Html/contents.html
taken from the splatalogue compilation\textsuperscript{5}. We have identified several lines in the JPL database\textsuperscript{6} (Pickett et al.\textsuperscript{7} 1998) corresponding to other transitions of molecules (CH$_2$NH, NH$_2$CHO, NH$_2$CN, CH$_3$CHO) known in Sgr B2 from other frequencies, notably in the 3-mm band in Jones et al.\textsuperscript{8} (2008a).

The RMS noise in the (Hanning smoothed) data cubes varies from 34 to 76 mK ($T_B$).

There are also a few other weaker lines detected (mostly at the Sgr B2 (N) and (M) cores), but as they are quite weak and we do not have confident line identifications, we do not consider them further here. Other projects are in progress to obtain line survey data for Sgr B2, notably the PRIMOS\textsuperscript{9} survey with the 100-m Green Bank Telescope (GBT) of Sgr B2 (N) which will cover this 7-mm band (Remijan et al.\textsuperscript{10} 2008). These line surveys have longer integration time and higher sensitivity, and are better for studying the weak lines in the cores than the mapping observations presented here.

To study the spatial distribution of the different lines, we have made integrated emission images (Figs. 1 and to 6). We integrated each data cube over a velocity range which included significant emission (above around 3 σ in the cubes) for each line, which means the velocity range is different for each line.

The integrated images in Figs. 1 to 6 are plotted as grey-scale, with the scale bar to the right in K km s$^{-1}$ ($T_B$). The contour levels are in equal linear steps, mostly 2 K km s$^{-1}$, but sometimes 5 or 10 K km s$^{-1}$, and 100 K km s$^{-1}$ for the very strong CH$_3$OH maser line at 36.17 GHz. We plot as fiducial marks the positions of radio sources as crosses and mid-IR sources as squares, as in Jones et al.\textsuperscript{11} (2008a). As the axes of Figs. 1 to 6 are Galactic coordinates, the north-south line of cores Sgr B2 (N), (M) and (S) is at a (Galactic) position angle around 45 degrees, with Sgr B2 (N) being the cross (radio source) near the centre at $l = 0.680$ deg, $b = -0.028$ deg, Sgr B2 (M) being the cross and square (radio and infrared source) below and to the right at $l = 0.667$ deg, $b = -0.036$ deg and Sgr B2 (S) the cross and square further below and to the right at $l = 0.657$ deg, $b = -0.041$ deg. The radio and infrared peaks are plotted (with the N, M and S labels) in Figs. 1 to 6 in equatorial coordinates.

We discuss these images in more detail below, in subsections 3.1 to 3.13.

For quantitative analysis of the differences in spatial distribution of the different lines, we have fitted the position of the peak emission in the data cubes, with the MIRIAD task maxfit, which fits the position with a parabolic fit to the spatial pixels around the peak pixel in the cube. This is similar to the analysis used in Jones et al.\textsuperscript{12} (2008a) for the 3-mm Sgr B2 Mopra imaging, but we only fit the strongest peak, not multiple peaks, as the resolution is lower here at 7 mm and much of the spatial structure is merged together. As the emission is typically complex and extended, we do not generally fit the spatial structure as gaussian peaks.

These peak positions are tabulated in Table 1, arranged in groups of similar lines, as plotted in Figs. 1 to 6. We note that due to absorption in some of the spectra, and line width differences across the area, that the position of the peak emission in the data cubes is not the same as the position of the peak of integrated emission.

The velocity structure was studied by fitting the spectrum in each data cube at the position of the pixel of strongest emission,

\caption{Summary of strong lines detected in the Mopra observations. The first column gives an approximate frequency we have used for labelling transitions in this paper. The second column identifies the species, and the third its transition. The last columns indicates the rest frequency and the database used for the identification: L, Lovas; S, splatalogue; J, JPL (see text). The rest frequencies with a * indicate the frequency used for lines corresponding to multiple transitions, most also indicated as group (gp) in the transition list.}
\end{table}
Table 2. Summary of peaks fitted to the lines. The lines are grouped into the same order as plotted in Figs. 1 and 3 to 6. The positions are the fits to the maximum in the channel of strongest emission, and the velocity centre, velocity width (FWHM) and peak are from gaussian fits at the brightest pixel of the line emission. Note that the velocity centres use the rest frequencies from Table 1 so will be confused for the groups of lines, and the velocity widths will be increased for such confused lines.

| Line ID molecule or atom | Rest Freq. (GHz) | Lat. peak (deg) | Long. peak (deg) | Veloc. centre (km s\(^{-1}\)) | Veloc. width (T\(_{1/2}\)) (K) | Peak position (GHz) |

\(^a\) line labelled as HCC\(^{13}\)CN a blend with HCC\(^{13}\)CCCN so larger line width and biased velocity  
\(^b\) SO line at band edge, fitted with fixed width, due to poor data  
\(^c\) CS line with self-absorption, fitted as two gaussians
Figure 1. The integrated emission images for the nine recombination lines of hydrogen H 59 α to H 51 α. In this figure and later images the crosses (+) denote the position of radio peaks and the open squares (□) positions of infrared peaks. The line of cores Sgr B2 (N), (M) and (S) is at a (Galactic) position angle around 45 degrees, with Sgr B2 (N) being the cross near the centre at $l = 0.680$ deg, $b = -0.028$ deg, Sgr B2 (M) being the cross and square below and to the right at $l = 0.667$ deg, $b = -0.036$ deg and Sgr B2 (S) the cross and square further below and to the right at $l = 0.657$ deg, $b = -0.041$ deg. For clarity, these cores are labelled in this figure, and later figures. The scale bar is in units of K km s$^{-1}$, for $\int T_A^* d\nu$.

3.2 HC$_3$N and $^{13}$C isotopologues

There are two lines of cyanoacetylene HC$_3$N, shown in Fig. 3, the 4–3 (36.39 GHz) and 5–4 (45.49 GHz) groups of transitions. The integrated emission is distributed on a ridge at higher latitudes than the Sgr B2 (N), (M) and (S) line (shown as crosses), that is to the north-west in equatorial coordinates, with the peak to the north of Sgr B2 (N). This is similar to the distribution of the HC$_3$N 3-mm lines 9–8, 10–9, 11–10 and 12–11 found in Jones et al. (2008a). It is also similar to the distribution of the 4–3 line in Lis & Goldsmith (1991) and Chung, Ohishi & Morimoto (1994), but these latter data covered smaller areas.

There are also three lines of the $^{13}$C isotopologues of HC$_3$N, the combined HCC$^{13}$CN and HCC$^{13}$CN 5–4 line (45.30 GHz), the H$^{13}$CCCN 4–3 (35.27 GHz) and H$^{13}$CCCN 5–4 (44.08 GHz) lines. These are all quite weak lines, but the 45.30 GHz line shows good agreement in spatial distribution to the HC$_3$N lines. The other two show fair agreement, but may be affected by scanning artifacts, with stripes along the longitude direction.

The mean peak position for the five lines is $l = 0.688$ deg, $b = -0.018$ deg, and, for the four lines not blended, mean velocity 66 km s$^{-1}$ and mean velocity width 28 km s$^{-1}$. (Note that the blended 45.30 GHz line has larger width, and anomalous velocity, in Table 2.)

3.3 HC$_5$N

There are seven lines of cyanodiacetylene HC$_5$N, shown in Fig. 3, the series from 12–11 (31.95 GHz) to 18–17 (47.93 GHz) transi-
Figure 3. The integrated emission images for two lines of HC₃N, three lines of $^{13}$C isotopologues of HC₃N, and seven lines of HC₅N.
tions. The lines are all quite weak, but the distribution is similar to that of HC$_3$N (above), best seen in the 31.95 GHz and 39.94 GHz lines, but broadly similar in the other lines, with the ridge to more positive latitudes than the radio sources (crosses). The mean peak position for the seven lines is $l = 0.690$ deg, $b = -0.019$ deg, mean velocity 66 km s$^{-1}$ and mean velocity width 22 km s$^{-1}$.

### 3.4 CH$_3$OH

There are three lines of methanol CH$_3$OH, shown in Fig. 4 the 4(−1,4) − 3(0,3) E (36.17 GHz), 7(0,7) − 6(1,6) A+ (44.07 GHz) and the 1(0,1) − 0(0,0) A+ plus 1(0,1) − 0(0,0) E (48.37 GHz) lines. The three line have quite different distributions, due to the complex collisional and radiative excitation processes of methanol.

The 36.17 GHz line can act as a (class I) maser, which gives the high brightness peak seen here in Fig. 4 Note that the peak is at the north cloud (Jones et al. 2008a) at $l = 0.693$ deg, $b = -0.024$ deg. The distribution is in good agreement with that found by Liechti & Wilson (1992) for this line, with higher resolution Efsherg 100-m telescope observations.

The 44.07 GHz line can also act as a (class I) maser. Mehringer & Menten (1997) have used the VLA at much higher resolution than the Mopra data here to map the distribution of this line. They find many maser and quasi-thermal peaks near the Sgr B2 (N) and (M) cores. The Mopra data (Fig. 4) are consistent with this distribution.

The 48.37 GHz line has a distribution that is similar to HC$_3$N (Fig. 4) and other 3-mm transitions of methanol in Jones et al. (2008a). This is not a maser transition so comparison with the 44.07 GHz line is instructive (Val’tts et al. 1991).

### 3.5 CH$_3$CHO

There are four lines of acetaldehyde CH$_3$CHO, shown in Fig. 4 the 2(0,2) − 1(0,1) E (38.50 GHz), 2(0,2) − 1(0,1) A (38.512 GHz), 2(1,1) − 1(1,0) E (39.36 GHz) and 2(1,1) − 1(1,0) A (39.59 GHz) lines.

The distribution of integrated emission from acetaldehyde is widespread, as found by Chengalur & Kanekar (2003). However, we find for these 7-mm lines that there is a deficit of emission near Sgr B2 (N) and (M), probably due to absorption. Chengalur & Kanekar (2003) find the 1(1,1) − 1(1,0) transition at 1065 MHz in emission near Sgr B2 (N), (M) and (S), which they attribute to a weak maser. The distribution of the four lines is similar, although the 39.36 and 39.59 GHz lines are weak. The emission peaks at the north cloud with mean peak position $l = 0.684$ deg, $b = -0.014$ deg, mean velocity 68 km s$^{-1}$ and mean velocity width 26 km s$^{-1}$.

### 3.6 NH$_2$CHO

There are two lines of formamide NH$_2$CHO, shown in Fig. 4 the 2(1,2) − 1(1,1) group (40.88 GHz) and the 2(0,2) − 1(0,1) group (42.39 GHz). The distribution of integrated emission is similar to that of acetaldehyde (above) with widespread emission, peaking at the north cloud (mean peak position $l = 0.683$ deg, $b = -0.010$ deg) and a deficit near Sgr B2 (N) and (M). This distribution is somewhat different to that of the formamide 5(1,4) − 4(1,4) line at 102.07 GHz in Jones et al. (2008a) which peaks on the ridge to the west of Sgr B2 (M), but this line is confused with the protonated formaldehyde H$_2$COH$^+$ 4(0,4) − 3(1,3) line (Ohishi et al. 1996).

### 3.7 SO

There is one line of sulphur monoxide SO, shown in Fig. 5 the 1(0) − 0(1) (30.00 GHz) line. There is widespread emission over the area, with strong absorption near Sgr B2 (M). This is in contrast to the 3-mm SO lines, where the emission is strongly peaked at Sgr B2 (M) in the 2(2) − 1(1) (86.09 GHz) and 2(3) − 1(2) (109.25 GHz) lines, and extended along the ridge-line to the west of Sgr B2 (M) in the 3(2) − 2(1) (99.30 GHz) line (Jones et al. 2008a; Goldsmith et al. 1987).

### 3.8 SiO and $^{29}$SiO

There are two lines of silicon monoxide SiO 1 − 0 v=0 (43.42 GHz) and the isotopologue $^{29}$SiO 1 − 0 v=0 (42.88 GHz) shown in Fig. 5. The integrated emission is widely distributed in both lines, with absorption near Sgr B2 (M) and (N), like the SO line (above).

The ratio between the isotopologue $^{29}$SiO and SiO, indicates that the SiO is optically thick. This leads to the differences in the integrated distribution, and fitted mean velocity and velocity width in Table 2 as the suppression of emission in the SiO line centre shifts the mean and increases the fitted width. The SiO 1 − 0 line distribution coincides with the peak labelled SiO+69.06 of this line in Martin-Pintado et al. (1997), and has similar absorption at Sgr B2 (M) and (N) seen in the 3-mm SiO 2 − 1 (86.85 GHz) line in that paper. It is also similar to the distribution of the SiO 2 − 1 line in Minn (2007) and Jones et al. (2008a), but the latter is at lower signal to noise.

We also have data for the maser lines SiO 1 − 0 v=1 (43.12 GHz) and 1 − 0 v=2 (42.821 GHz) but did not detect these lines above a 3 σ level of 0.10 K, although these lines have been detected in Sgr B2 by, for example Zapata et al. (2009). If the v=1 line was as strong as that reported by Zapata et al. (2009), corresponding to 0.18 K, it would have been detected here, but such masers are variable, so it is quite plausible that the strength has changed.

### 3.9 CS, $^{13}$CS and C$^{34}$S

There are three lines of carbon monosulphide CS 1 − 0 (48.99 GHz) and the isotopologues $^{13}$CS 1 − 0 (46.25 GHz) and C$^{34}$S 1 − 0 (48.21 GHz) shown in Fig. 5. Like the SiO line above, there is widespread emission, with absorption near Sgr B2 (M) and (N). There are optical depth effects which make the integrated emission of the CS line and the isotopologues $^{13}$CS 1 − 0 and C$^{34}$S different. The peaks in the data cubes (Table 2) are near Sgr B2 (M) at peak position $l = 0.661$ deg, $b = -0.041$ deg (mean of the five lines). The CS line shows absorption, so is fitted in Table 2 as two gaussians, offset in velocity. The peaks of integrated emission (Fig. 5) are at different positions, due to the effects of absorption. These distributions are similar to that found by Jones et al. (2008a) for the 3-mm lines CS 2 − 1 (97.98 GHz) and the isotopologues $^{13}$CS 2 − 1 (92.49 GHz) and C$^{34}$S 2 − 1 (96.41 GHz). The CS 1 − 0 (48.99 GHz) line has also been mapped by Sato et al. (2003), with the Nobeyama 45-m telescope at higher resolution, showing similar line distribution.
Figure 4. The integrated emission images for three lines of CH$_3$OH (methanol), four lines of CH$_3$CHO and two lines of NH$_2$CHO.

3.10 CCS

There are two lines of dicarbon monosulphide CCS shown in Fig. 5, the 3,2 – 2,1 (33.75 GHz) and 4,3 – 3,2 (45.38 GHz) lines. The emission peaks in the north cloud, with mean peak position $l = 0.688$ deg, $b = -0.014$ deg, mean velocity $66$ km s$^{-1}$ and mean velocity width $21$ km s$^{-1}$. The integrated emission avoids the Sgr B2 (M) and (N) area, but this may be due to absorption, as shown in the CCS 45.38 GHz line (Fig 5). This is different to the distribution of the CCS 7,6 – 6,5 (81.505 GHz) line shown by [Kuan & Snyder (1994)], at higher resolution, which peaks near Sgr B2 (M) and (S).

3.11 CH$_3$CN

There is one line of methyl cyanide CH$_3$CN, shown in Fig. 5 the 2(0) – 1(0) group (36.80 GHz). The emission also peaks in the north cloud, and shows the ridge in the integrated emission to the north-west of Sgr B2 (N) and (M), similar to that in the CH$_3$CN 5 – 4 (91.99 GHz) and 6 – 5 (110.38 GHz) lines in [Jones et al. (2008a)] and the 5 – 4 line in [de Vicente, Martin-Pintado & Wilson (1997)]. There may also be some absorption in the 2(0) – 1(0) line here, around Sgr B2 (N) and (M), not just a deficit of emission.

3.12 OCS

There are two lines of carbonyl sulphide OCS shown in Fig. 6, the 3 – 2 (36.49 GHz) and 4 – 3 (48.65 GHz) lines. The emission peaks in the north cloud, with mean peak position $l = 0.684$ deg, $b = -0.028$ deg, mean velocity $63$ km s$^{-1}$ and mean velocity width $22$ km s$^{-1}$, although there are some differences in distribution between the two transitions. The distribution is similar to the 7 – 6 (85.14 GHz), 8 – 7 (97.30 GHz) and 9 – 8 (109.46 GHz) lines [Jones et al. (2008a)], with the ridge near Sgr B2 (N) and (M).
3.13 HNCO and HOCO$^+$

There is one line of isocyanic acid HNCO the 2(0,2) – 1(0,1) group (43.96 GHz) and one of protonated CO$_2$ HOCO$^+$ 2(0,2) – 1(0,1) (42.77 GHz) shown in Fig. 6. These lines peak at the north cloud, so the two molecules are discussed here together.

The HNCO 43.96 GHz distribution is similar to that of the 4(0,4) – 3(0,3) (87.93 GHz) and 5(0,5) – 4(0,4) (109.91 GHz) lines in Jones et al. (2008a) and Minh et al. (1998). Observations of the 4(0,4) – 3(0,3) line over a wider area (albeit at lower resolution) are shown in Minh & Irvine (2006) along with discussion of this north cloud (called the 2'N HNCO peak by them). There are also observations of the 1(0,1) – 0(0,0) (21.98 GHz) line in Wilson et al. (1996), with similar distribution.

The HOCO$^+$ 42.77 GHz distribution similar to that of the 4(0,4) – 3(0,3) (85.53 GHz) and 5(0,5) – 4(0,4) (106.91 GHz) lines in Jones et al. (2008a), Minh et al. (1998) and Minh, Irvine & Ziurys (1988) and similar to the HNCO lines, highlighting the chemical distinctness of this north cloud (Wilson et al. 1996) from the Sgr B2 (M) and (N) area.

3.14 CH$_2$NH, NH$_2$CN, HCS$^+$ and CH$_2$CN

Finally, there is one line of each of the methylenimine CH$_2$NH 3(0,3) – 2(1,2) group (35.07 GHz), cyanamide NH$_2$CN 2(1,2) – 1(1,1),v=0 (39.73 GHz), thioformyl HCS$^+$ 1 – 0 (42.67 GHz) and the cyanomethyl radical CH$_2$CN 2 – 1 group (40.25 GHz) shown in Fig. 6.

The CH$_2$NH 35.07 GHz line distribution peaks near Sgr B2 (M), and is similar to the distribution of the 4(0,4) – 3(1,3) (105.79 GHz) line in Jones et al. (2008a). The latter being at higher resolution resolves the structure better, showing the peak at Sgr B2 (N) whereas the fitted peak in the 35.07 GHz line is near
Figure 6. The integrated emission images for two lines of OCS, and one line each of HNCO, HOCO$^+$, CH$_2$NH, NH$_2$CN, HCS$^+$ and CH$_2$CN.

Sgr B2 (M). There are likely to be excitation differences between the two cores.

The NH$_2$CN 39.73 GHz line peaks at the north cloud, with the ridge to the north-west of Sgr B2 (M), with a distribution similar to that of the 5(1,4) – 4(1,3) (100.63 GHz) line [Jones et al. 2008a], although the image there is noisy and affected by scanning stripes.

The HCS$^+$ 42.67 GHz line is quite weak, but has an extended distribution. Not much is known on the distribution of this ion in Sgr B2, but it is plausible that the distribution is similar to that of CS (e.g. Fig. 5, subsection 3.9).

The distribution of integrated emission of the CH$_2$CN 40.25 GHz line is extended, with likely absorption near Sgr B2 (N). There are some stripes in the integrated emission in the longitude scanning direction. The distribution differs from that of CH$_2$CN (Fig. 5, subsection 3.11) which may indicate that the two molecules have quite different formation routes and destruction paths [Irving et al. 1988; Turner et al. 1994], despite their apparent similarity.

3.15 Summary of peak positions

The peak positions of the 7-mm lines in the data cubes tabulated in Table 2 are plotted in Fig. 7. The hydrogen recombination lines (filled triangles in Fig. 7) peak between Sgr B2 (N) and (M), as discussed in subsection 3.1 and shown in Fig. 2. The molecular lines mostly peak at the north cloud.

We attribute the molecular line distributions in this 7-mm band to a combination of the effect of emission, from an extended cloud centred to the east of Sgr B2 (N) and (M), and absorption due to the free-free continuum at Sgr B2 (N) and (M). We consider this further in the Discussion (Section 5) and in the next section (Section 4), where we analyse the spatial distributions in a relatively objective way.

© 2010 RAS, MNRAS 000, 1–18
The contours are from the CH$_3$OH molecular peaks and filled triangles for the H radio recombination lines. This describes the multi-dimensional data set by linear combinations of the data that describe the largest variance (the most significant features). This has been used by Ungerechts et al. (1997) to identify and quantify the features of large data sets is Principal Component Analysis (PCA), see e.g. Heyer & Schloerb (1997). In the context here, we can use PCA to describe the large number of images, with a smaller set of images which contain the most significant features. This has been used by Ungerechts et al. (1997) for the OMC-1 ridge, and more recently by us for the G333 molecular cloud (Lo et al. 2009) and the Sgr B2 area with 3-mm molecular lines (Jones et al. 2008c).

We have implemented the PCA processing in a PYTHON script, with the PCA module$^8$ and pyFITS$^9$ to read and write the FITS images.

The images of the three most significant components of the 7-mm integrated emission are shown in Fig. 8. The first four components describe respectively 56, 14, 9 and 4 percent of the variance in the data. These components are statistical descriptions of the integrated line images, not necessarily physical components of Sgr B2. However, they do highlight the physical features in a useful way.

The first component (Fig. 8) highlights emission from the north cloud and ridge. The second component highlights absorption (or emission) from Sgr B2 (N) and (M), and also some differences in the north cloud. The third component highlights differences in emission to the south. The fourth component (not shown here in Fig. 8) highlights differences in emission from Sgr B2 (N).

The relations between the molecular integrated emission images, and the PCA images are shown in Fig. 9 as vectors of the projection of the data images on the axes of the PCA image. The molecules are labelled with numbers, for clarity, in these plots. All of the data images are positively correlated with the first PCA image, except for SO (37). The greatest positive correlation with the second PCA component are for SO (37) and SiO (36), which have strong absorption at Sgr B2 (N) and (M). The greatest negative correlation with the second PCA component are for CH$_3$OH (6) and the CH$_3$OH 44.07 GHz line (12, with some maser emission), which have emission at Sgr B2 (N) and (M). The greatest positive correlation with the third PCA component are for the CH$_3$CHO 38.512 GHz line (7) and the H$^{12}$CCCN 35.27 GHz line (17), and greatest negative correlation with the third PCA component are for NH$_2$CN (33) and CS (15), highlighting more or less emission to the south, relative to the other lines.

We used the integrated emission images for 37 molecules here in the PCA, excluding CH$_3$CN (as it is probably affected by the scanning ripples), and not including the radio recombination lines (RRLs), as they are due to a different physical mechanism. However, we have also calculated the PCA for the 46 integrated emission images, including the RRLs, find very similar results. The first four components then describe respectively 49, 24, 8 and 3 percent of the variance in the data, with the PCA images quantitatively very similar, with the major difference being the second component image having a stronger peak at Sgr B2 (N) and (M), describing the RRLs, and positive rather than negative. However, the sign of the component images is not physically significant.

The PCA images from these Sgr B2 7-mm lines can be compared to those found for the Sgr B2 3-mm lines from Jones et al. (2008a) in Fig. 10. Jones et al. (2008a). The 3-mm PCA images are at higher resolution.

The first two PCA component images are similar: the first highlighting the ridge and north cloud, and the second highlighting absorption at Sgr B2 (N) and (M). The second PCA component at 3-mm also includes emission to the south-west, as some of the strongest lines at 3-mm, such as HCN, HCO$^+$ and HNC are optically thick with both absorption at Sgr B2 (N) and (M) and the south-west area relatively stronger (as the the main emission is relatively weaker due to the high optical depth). The third 3-mm PCA component highlights the north cloud, and Sgr B2 (M). As PCA is a statistical tool, it is not expected that the higher PCA images, of lower statistical weight, should be the same from the independent 7-mm and 3-mm data. However, the PCA images from the 3-mm and 7-mm data do show quite similar spatial features, albeit distributed differently amongst the PCA images: ridge, north cloud, Sgr B2 (N) and Sgr B2 (M).

5 DISCUSSION

We can consider the distribution of the spectral lines in terms of physical components of the Sgr B2 complex: the hot cores Sgr B2 (N), (M) and (S), and the extended envelope. These are related to the Principal Components discussed in the last section, but are not the same decomposition of structure into features. In Jones et al. (2008a) we identified seven features. Of these, the extended ridge and north cloud are related to the extended envelope of Sgr B2 (Jones et al., 2008a), which is traced by the dust seen at sub-mm wavelengths (Fig. 11). The hot cores Sgr B2 (N), (M) and (S) are
Figure 8. The first three images from the Principal Component Analysis (PCA) for the 7-mm lines, describing 56, 14 and 9 percent of the data variance respectively. The first image highlights emission from the north cloud and ridge, the second image highlights absorption (or emission) from Sgr B2 (N) and (M) and the third image highlights differences in emission to the south.

Figure 9. The component vectors of the integrated line images in the decomposition of the data into the PCA images, shown with successive pairs of PCA images. The vectors are labelled with numbers, rather than molecule names, for clarity of presentation, with the molecules listed in alphabetical order: 1, $^{13}$CS; 2, $^{29}$SiO; 3, $^{34}$S; 4 and 5, two lines of CCS; 6, CH$_3$NH; 7 to 10, four lines of CH$_3$CHO; 11, CH$_3$CN; 12 to 14, three lines of CH$_3$OH; 15, CS; 16 and 17, two lines of H$^{13}$CCCN; 18 to 24, seven lines of HC$_3$N; 25, HCC$^{13}$CN; 26 and 27, two lines of HC$_3$N; 28, HCS$^+$; 29, HNCO; 30, HOCO$^+$; 31 and 32, two lines of NH$_2$CHO; 33, NH$_2$CN; 34 and 35, two lines of OCS; 36, SiO, and; 37, SO.

Figure 10. The first three images from the Principal Component Analysis (PCA) for the 3-mm lines (lower) from Jones et al. (2008a). These 3-mm images are similar to those in Jones et al. (2008b), rotated into Galactic coordinates for easier comparison to the 7-mm images. The first image highlights emission from the north cloud and ridge. The second image highlights absorption (or emission) from Sgr B2 (N) and (M) and emission from the south-west. The third image highlights the north cloud and differences in emission from Sgr B2 (M).
denser and warmer, and so have different chemistry, so they are prominent in particular molecules, as shown in Fig. [6] by CH$_3$NH. In the 7-mm band data here, there is also often absorption in the area around Sgr B2 (N) and (M) related to the radiative transfer of the continuum free-free emission through the molecular gas.

To better describe the quantitative properties of these physical components of Sgr B2, we have considered in the Appendix continuum data (imaging and photometry) from the radio, through sub-mm to mid-IR wavelengths, from the literature, plus some of our own (as yet unpublished) radio and sub-mm data, and data from public archives. We have fitted the spectral energy distribution (SED) of the Sgr B2 (N), (M) and (S) cores, and the extended envelope, using the imaging to set the angular size of the components, to derive parameters such as dust temperature.

The integrated line emission $\int T_Bdv$ plotted in Figs. [3] to [6] is related the column density of the molecule in the upper state of the transition $N_u$ by

$$N_u = (8\pi\nu^2/k_hc^3A_{ul}) \int T_Bdv$$

where $A_{ul}$ is the Einstein coefficient, and assuming optically thin emission (optical depth $\tau \ll 1$). This is related to the total column density of the molecule $N$, assuming local thermodynamic equilibrium (LTE) by

$$N = N_u(Q_T/g_u)\exp(E_u/kT_C)$$

where $g_u$ is the statistical weight of the upper level, $Q_T$ is the partition function at excitation temperature $T_C$ and $E_u$ is the energy of the upper level. This analysis also assumes the line emission fills the beam (filling factor unity) and that the line brightness temperature $T_B$ is much greater than the continuum brightness temperature $T_C$.

In this simple case, then, the integrated line emission $\int T_Bdv$ traces the molecule column density $N$, and we can use this to trace chemical variations in the Sgr B2 complex. However, the simplifying assumptions are often not valid, so the relation is more complicated.

Firstly, some transitions are not in LTE, as shown by the differences between the three methanol (CH$_3$OH) lines in Fig. [2] which include maser transitions. Secondly, even if the lines are in local thermodynamic equilibrium, there are large gradients in the kinetic temperature $T_K$ and radiation environment (corresponding to radiation temperature $T_r$) giving gradients in excitation temperature $T_{ex}$. So transitions from higher energy states will preferentially highlight higher temperature regions. Thirdly, the lines are often not optically thin, so that the optically thick emission is not simply proportional to the column density $N_u$, in the sense that the integrated intensity saturates for high optical depth in regions of high column density. Fourthly, we have, so far, ignored the full radiative transfer model in which background continuum radiation can be absorbed by the molecules in the cloud, as well as the molecules emitting. With a background continuum source of brightness temperature $T_C$, we obtain

$$T_B = T_{ex} - \exp(-\tau) + T_C \exp(-\tau)$$

$$\approx T_C + (T_{ex} - T_C) \tau$$

Typically, the spectral line data (as in this paper) are baseline subtracted, to be the line only, but the effect of the background continuum is to reduce the line intensity, and for $T_C > T_{ex}$ the line becomes negative in intensity, i.e. is seen in absorption.

Most of the lines presented here are dominated by emission from the extended, cooler ($T_{dust} \sim 20$ K), envelope, rather than the compact hot cores. The scale of this envelope is around 2 arcmin, but elongated north-south in equatorial coordinates (as shown in the mid-IR, Fig. [A1]). This envelope is centred to the east of the line of the hot cores Sgr B2 (N), (M) and (S), with the north cloud to the north of the hot cores. In Galactic coordinates, this corresponds to a ridge, wrapping around the hot cores, as shown in the first principal components of the 7-mm (Fig. [5]) and 3-mm lines (Fig. [10]). There are also chemical differences, for example with HNCO and HOCON preferentially found (Fig. [6]) in the north cloud. The effective spatial scale of the stronger, optically thick lines, such as SO, SiO and CS (Fig. [5]) is larger, with the emission filling the whole 6 $\times$ 6 arcmin$^2$ area imaged, as the central peak emission saturates (and there is absorption). The optically thin isotopologues ($^{29}$SiO, $^{13}$CS and $^{34}$S, Fig. [5]) are better tracers of the extent of the envelope.

The recombination lines (Fig. [1]) show the distribution of the 7-mm free-free radio continuum, assuming that there is not a very large spatial variation in the line to continuum ratio (so that the line emission traces the continuum distribution). The deconvolved angular size (from these recombination lines) is 2.2 $\times$ 0.9 arcmin$^2$, and the fit to the radio flux densities (Figs. [A2] and Table [A2]) shows that around half the flux comes from the extended envelope and half from the compact hot cores. The spatial distribution along the line of sight of the Sgr B2 components is not well constrained, but the spectral energy distribution (SED) fitting (Appendix) does indicate that Sgr B2 (N) is behind at least part of the dust envelope. Many of the 7-mm molecular lines in Figs. [3] to [6] show absorption centred near Sgr B2 (N) and (M) which matches well the position and scale of the 7-mm free-free continuum (as probed by the recombination lines in Fig. [1]).

With a flat spectral index ($\alpha = -0.17 \pm 0.07$ for the total free-free) in the optically thin regime, the continuum brightness temperature falls steeply with frequency as $T_C \propto \nu^{-\alpha}$. The conditions for absorption of the continuum radiation, by the intervening cool envelope ($T_C$ significant compared to $T_{ex}$), are commonly met in these 7-mm data, as highlighted in the second principal component of Fig. [5]. The molecules with the most significant absorption are SO, SiO, $^{29}$SiO, CS, CH$_3$CHO, NH$_3$CHO and CCS (although for the last three molecules this is less clear in some of the lower signal-to-noise lines).

Similar absorption occurs for the 3-mm data of Jones et al. [2008] (seen in the second principal component of Fig. [10]). At these higher frequencies, the absorption at the hot cores Sgr B2 (N) and (M) dominates over the absorption due to the extended envelope. The resolution is higher, the cores contribute a larger fraction of the free-free continuum, and have a higher brightness temperature.

In both the 7-mm and 3-mm molecular lines, there are also lines that peak at the Sgr B2 (N) and (M) hot cores, due to their different chemical conditions and higher temperature. In the 7-mm data here, the most prominent ‘hot core’ lines are from CH$_3$NH, and the 44.07 GHz transition of CH$_3$OH which includes maser emission (Mehringer & Menten 1997).

The chemistry of molecular clouds is complex (Herbst & van Dishoeck 2009), particularly those associated with star-formation, like Sgr B2. Broadly, the chemistry of regions that are heated by star formation to become hot cores can be described in three stages: the cold, warm up and hot core stages.

In the cold stage, there are gas-phase reactions plus grain-surface reactions, with a lot of the complex chemistry occurring between molecules sticking on the ice-grains. In the warm up stage, as
the material forming the protostar collapses, there is heating (from 10 K to a few hundred K), and the grain mantles sublime, releasing different molecules at different temperatures and hence times. There are further gas-phase and grain-surface reactions occurring with modified chemical abundances and hotter temperatures. In the last hot core stage, with temperatures 100 to 300 K, the ices have sublimed, so there is only gas-phase chemistry.

The overall chemical evolution is complicated, and time dependent, so detailed models typically consider a particular phase. A recent gas-grain warm up model, of relevance to Sgr B2 (N) is Garrod, Weaver, & Herbst (2008).

The observed spectral-line data can be compared to such models, and constrain models, but this is not straightforward (Herbst & van Dishoeck 2009). For a particular position, or an unresolved source, the observed antenna temperature can be converted to a source brightness temperature, using the source size or filling factor. This can be converted to a molecular column density (or abundance relative to e.g. CO) using the excitation temperature $T_e$ and optical depth $\tau$ (preferably using constraints from other lines). A better way to analyse the molecular line data is to construct a physical model of the source (see Herbst & van Dishoeck 2009, Figure 4) and calculate the full non-LTE statistical equilibrium excitation of the molecule through the physical structure.

For the Sgr B2 complex data presented here, with the hot cores, and cooler envelope, we do not attempt such a detailed radiative transfer model, but simply point out the broad features required in such a model, namely the physical components (see Appendix) and the effects of optical depth and absorption. We show by the line distribution images that there are significant spatial differences in the chemical distribution, that can be interpreted in terms of the cool, warm up and hot core ‘stages’ of the chemical models, with different parts of the Sgr B2 complex having different heating conditions and history.

6 SUMMARY

We have undertaken a line imaging survey of the Sgr B2 region from 30 to 50 GHz (the 7-mm band) with the 22-m single-dish Mopra telescope. This complements the Mopra 3-mm line imaging of Sgr B2 presented in Jones et al. (2008a). Integrated emission images of 47 lines are presented: 38 molecular lines and 9 radio recombination lines.

The distributions of individual lines are discussed, and we have studied the similarities and differences between the lines with principal component analysis (PCA). The major features from the PCA are extended emission from the ridge and north cloud to the north and east of the Sgr B2 (N) and (M) hot cores, and absorption near Sgr B2 (N) and (M). These statistical features are interpreted in terms of the physical components of the Sgr B2 complex (discussed in the appendix) of the extended low temperature envelope, and compact hot cores Sgr B2 (N), (M) and (S). The 7-mm free-free emission in the area of Sgr B2 (N) and (M) is absorbed in this line-of-sight by the envelope.

ACKNOWLEDGMENTS

The Mopra telescope is funded by the Commonwealth of Australia as a National Facility managed by CSIRO as part of the Australia Telescope. The UNSW-MOPS Digital Filter Bank used for the observations with the Mopra telescope was provided with support from the Australian Research Council (ARC), together with the University of New South Wales, University of Sydney and Monash University. We also acknowledge ARC support through Discovery Project DP0879202. PAJ acknowledges partial support from Centro de Astrofisica FONDAP 15010003 and the Gemini-CONICYT Fund. We thank John B. Whiteoak for the 1.2-mm SIMBA data, and an anonymous referee for useful comments that improved the presentation of the paper.

APPENDIX A: THE COMPONENTS OF SGR B2

The Sgr B2 complex is very complicated, with many physical components distinguishable at high resolution, see for example Mehringer & Menten (1997) and Gaume et al. (1995). However, for many observations with resolution of order tens of arcseconds (Fig. A1) it is common, and physically useful, to consider the three dense cores Sgr B2 (N), (M) and (S), and distinguish them from the larger and less dense envelope.

The three dense cores are prominent in both the radio free and sub-mm dust continuum, as shown in Fig. A1 and the (M) and (S) cores are prominent in the mid-infrared. The sub-mm dust distribution also shows the extended component, centred slightly to the west of the line of dense cores, with an extension to the north. As we pointed out in Jones et al. (2008), many of the 3-mm molecular lines follow the ridge of this extended dust component, while other lines are associated with the dense cores. We find similar distributions here for the 7-mm molecular lines, so for more detailed quantitative discussion of these 7-mm and 3-mm line data, we have undertaken an analysis of the Sgr B2 continuum data.

The structure of the Sgr B2 complex has been analysed by Gordon et al. (1993) using the spectral energy distribution (SED) of the total complex and components FIR1, FIR2 and FIR3 in their nomenclature, corresponding to (N), (M) and (S).

The peak in the SED due to dust is modelled as a Black Body modified by the optical depth $\tau_\nu$ of the dust, so the flux density $S_\nu$ divided by the source solid angle $\Omega$ is $S_\nu/\Omega = B_\nu(T)(1 - \exp(-\tau_\nu))$, where $B_\nu(T)$ is the Planck function (Wilson, Rohlfs, Hüttemeister 2009). The dust optical depth is assumed to be proportional to the gas column density, with some empirical scaling factor. The model from Mezger, Zylka & Wink (1990) is used with $\tau_\nu = (N_H/1.4 \times 10^{20} \text{cm}^{-2})(\lambda/\mu \text{m})^{-2}b(Z/Z_\odot)$, where $N_H$ is the total hydrogen column density, $(Z/Z_\odot)$ is the metallicity, assumed 2 for the Galactic Centre and $b$ is a dust parameter, with $b = 3.4$ for hydrogen number density $n_H \gtrsim 10^6 \text{cm}^{-2}$ and $b = 1.9$ for $n_H \lesssim 10^6 \text{cm}^{-2}$.

The observed flux densities in the dust SED can be fitted with 3 parameters; temperature $T$, solid angle $\Omega$, and the wavelength $\lambda_{\nu=1}$ at which the optical depth is unity, related by the above equation to the column density $N_H$. (In this model the power-law index of the dust optical depth is $\beta = 2$: other models can have different power law slopes $\beta$, but we leave $\beta$ fixed here to reduce the number of free parameters in the fit.)

The SED model assumed is simple, with constant temperature $T$, over a uniform dust density distribution of solid angle $\Omega$, but this is a common assumption in fitting sub-mm dust SEDs. It also has the advantage of a simple analytic form that can be fitted. We recognise that the dust distribution and temperature are not uniform (as shown in higher resolution studies) but argue that the characteristic temperature, density and other parameters derived (Table A2) are useful for quantitative analysis.

We plot in Fig. A2 the SED of the Sgr B2 components, using the data from Gordon et al. (1993) plus some additional data, from more recent observations.

We include fluxes from Kuan, Mehringer & Snyder (1996) for the compact components in the 3-cm and 3-mm bands (combining their N and N’ into the one source). We also include mid-infrared fluxes from the MSX catalogue Baby Gator interface.10

We have fitted data from our own observations with the ATCA.
Figure A1. The continuum images of the Sgr B2 complex in radio (ATCA 1.54 GHz), sub-mm (SCUBA 850 μm) and mid-infrared (MSX 21 μm), showing the Sgr B2 (N), (M) and (N) cores. The radio and mid-infrared trace star formation, with some extra compact features, and extended emission to the south-east. The sub-mm traces warm and cold dust, including diffuse emission around the cores. Note that these images are in equatorial coordinates, rather than Galactic coordinates used in the main body of this paper, but the crosses for radio peaks and open squares for infrared peaks are used as fiducial marks.

Figure A2. The spectral energy distribution (SED) of the Sgr B2 components (N), (M), (S) and total, from the radio to the infrared, following Gordon et al. (1993), with some additional data. The dashed lines are our schematic fits to the SED, but we note that there are problems using fluxes from the literature with a wide range of spatial resolutions so that the $\chi^2$ value of the model fits are poor. The plot for the total flux has a long dashed line for the total flux points, and a shorter dashed line for the extended envelope which contains most of the flux. The plot for Sgr B2 (N) includes 3-sigma upper limits, from Spitzer MIPS at 70 and 24 micron, and MSX at 21 micron.
at 1.54 GHz (Fig. A1) and 36 GHz (Fig. 2) and with SIMBA on SEST at 1.2 mm. The fitting was done with multiple gaussians using the task imfit in the MIRIAD package, to obtain angular size information as well as flux densities.

We have also fitted data obtained as FITS images from several public databases. In the radio we obtained VLA images at 20 cm, 3.6 cm, 9 GHz (3.3 cm) and BIMA data at 3 mm from the Astronomy Digital Image Library (ADIL). In the sub-mm we obtained JCMT SCUBA images at 450 and 850 μm and recent CSO BOLOCAM images at 1.1 mm (Bally et al. 2010). In the mid-infrared we obtained MSX images at 8, 12, 15 and 21 μm, Spitzer MIPS images at 24 and 70 μm and IRAS reprocessed HIRES images at 60 and 100 μm. The recent paper (Bally et al. 2010) discusses the BOLOCAM 1.1 mm data, and shows the Spitzer 24 μm as a greyscale in their Figure 18 with 1.1 mm contours. They also show 350 μm CSO SHARC-II data, but do not quote fluxes (and we did not have access to the 350 μm from public archives).

The extra flux density data are summarised in Table A1. The limits for Sgr B2 (N) at 70, 24 and 21 μm are 3-sigma upper limits (see later discussion).

The flux density data (Fig. A2) show two physical components, the dust peak around 1.5 THz (200 μm) and the optically thin free-free emission between 3 and 100 GHz. There are, however, problems in using flux densities obtained from data obtained with a range of spatial resolutions. For the fitting of the complex structure with the components Sgr B2 (N), (M) and (N), and total flux, different amounts of flux will be included depending on the size of the telescope beam (as the four components are a simplification). This leads to discrepancies in the flux densities, even considering the quoted uncertainties. We have fitted models to the SEDs, despite this, but note that the reduced χ² of the fits are high.

For the free-free component, we have fitted power laws over the frequency range up to around 100 GHz, excluding some points for Sgr B2 (N) and the total which show some upturn due to the dust component. For the dust component we fitted the 3-parameter model discussed above. For Sgr B2 (N), as we discuss below, we also follow Gordon et al. (1993) in including an extra absorption term for dust along the line of sight, making a 4-parameter fit $S_{ν} = \Omega B_{ν}(T)(1 - \exp(-τ_{ν,1}))\exp(-τ_{ν,2})$. The dust fit used the data around 100 GHz for Sgr B2 (N) and the total, after correction for the free-free component. The fitting was done in the GnuPlot package, which uses the nonlinear least-squares (NLLS) Marquardt-Levenberg algorithm. For the total flux, we fitted the data after subtracting the models for the compact components Sgr B2 (N), (M) and (S), so that we were actually fitting the model to the extended envelope. The model fits for both the total flux and the extended envelope are both plotted in Fig. A2 and we note that for most of the frequency range, the extended component dominates the total flux.

For the free-free component, we find spectral indices of $−0.02 ± 0.03, 0.22 ± 0.02, 0.04 ± 0.16$ and $−0.32 ± 0.12$ for the components Sgr B2 (N), (M), (S) and the extended envelope respectively, and flux densities at 30 GHz 7.1 Jy, 9.9 Jy, 0.62 Jy and 17.7 Jy respectively. Note that this indicates that around half the flux is in the extended component which may be missed by the interferometric observations (e.g. Fig 7). We do attribute the radio emission from 3 to 100 GHz in the compact components to optically thin free-free emission, with basically a flat spectrum, although the rising spectrum of Sgr B2 (M) may indicate some of the subcomponents are ultracompact H II regions with the turnover from optically thick to optically thin above 10 GHz. The spectrum of the total Sgr B2 flux is flat (spectral index $−0.17 ± 0.07$), but when we subtract the compact components, notably Sgr B2 (M) with the rising spectrum, the residual extended component has a somewhat steeper spectrum.

There has been some discussion of non-thermal radio emission from Sgr B2 by Hollis et al. (2007), Crocker et al. (2007) and Protheroe et al. (2008). We agree with Lang, Palmer & Goss (2008) and Protheroe et al. (2008) that due to the complex structure of Sgr B2, it is difficult to measure the radio spectral index accurately by combining observations with different resolutions which may include different features. In particular, the fluxes measured with the GBT by Hollis et al. (2007) for Sgr B2 (N) will include flux from the extended component, to a greater extent at the lower frequencies with the larger beam.

The fits to the dust components, for three free parameters $T$, $Ω$ and $λ_{ν=1}$ gave similar results to that of Gordon et al. (1993), as expected since the data used here is based on their compilation. However, there are quite large uncertainties in derived $Ω$ and $λ_{ν=1}$, and the two parameters are highly correlated. We decided, therefore, to constrain the fits by using a fixed derived value for the dust solid angle $Ω$ obtained using the extra spatial information from the sub-mm images. This fit to two free parameters ($Ω$ and $λ_{ν=1}$) gives similar reduced χ² to the three free parameter fits, and only changes the fitted temperature $T$ by a few K.

We used the geometric mean of the deconvolved sizes from the SCUBA 450- and 850-μm images (resolution 7.5 and 14 arcsec), and the 1.3-mm IRAM 30-m image (resolution 11 arcsec), giving gaussian half-widths 10.2, 11.2 and 10.2 arcsec for Sgr B2 (N), (M) and (S), showing how the extended component dominates the total flux.

Table A2. Parameters for the Sgr B2 components fitted from the SEDs, and derived from these fits. From the fit to the optically-thin free-free part of each spectrum, we obtain the spectral index $\alpha_{ff}$ and the flux density $S_{30}$ at reference frequency 30 GHz. We choose to fix the angular size of the dust component to that measured from the sub-millimetre images, and derive the dust temperature $T_d$, and turnover wavelength $\lambda_{\tau=1}$ from the dust peak in the spectrum. The total hydrogen column density $N_H$, number density $n_H$ and mass $M_H$ are derived from the dust spectrum fits, as described in the text.

| Component | $\alpha_{ff}$ | $S_{30}$ | $\Omega$ | $T_d$ | $\lambda_{\tau=1}$ | $N_H$ | $n_H$ | $M_H$ |
|-----------|--------------|----------|----------|------|-------------------|------|-------|-------|
|           | Jy           | fixed arcsec$^2$ | pc | K | $\mu m$ | $10^{24}$ cm$^{-2}$ | $10^9$ cm$^{-3}$ | M$_\odot$ |
| N         | -0.02 ± 0.03 | 7.1 | 117 | 0.40 | 65 ± 17 | 740 ± 150 | 12 | 8.9 | 8600 |
| M         | 0.22 ± 0.02  | 9.9 | 138 | 0.43 | 50 ± 1  | 680 ± 70  | 9.6 | 6.8 | 8400 |
| S         | 0.04 ± 0.16  | 0.62 | 118 | 0.40 | 48 ± 1  | 230 ± 30  | 1.1 | 0.87 | 850  |
| envelope  | -0.32 ± 0.12 | 17.7 | 17400 | 4.5 | 24 ± 2  | 280 ± 40  | 3.0 | 0.19 | 32000 |

and (S).\footnote{We did not include deconvolved sizes from the BOLOCAM 1.1-mm or SIMBA 1.2-mm images, as the images were lower resolution (33 and 24 arcsec) and hence the deconvolved sizes were much less accurate.} We therefore used solid angles $\Omega = 1.133\theta^2$ of 117, 138 and 118 arcsec$^2$ for Sgr B2 (N), (M) and (S). For the extended component, we used the geometric mean of effective fitted solid angles from the SCUBA 450- and 850-$\mu$m, BOLOCAM 1.1-mm and 1.3-mm IRAM-30-m images, which is $\Omega = 1700$ arcsec$^2$.\footnote{The SIMBA 1.2-mm image may suffer from spatial filtering in the data reduction, affecting the extended structure.}

The results from the dust spectrum fits, with $\Omega$ fixed, and two free parameters $T_d$ and $\lambda_{\tau=1}$ are given in Table A2.

For Sgr B2 (N) we find, as pointed out by \cite{Gordon:1993}, that the extra line-of-sight absorption component to the model is needed, making in this case then a three parameter fit. If we fix the angular size $\Omega$ at that measured, then the extra absorption component to the model is clearly required: the reduced $\chi^2$ of the fit without the absorption (7.7) is substantially greater than with the absorption included (4.4), and the fit is clearly poor for the sub-mm range.

The turnover wavelength is fitted as $\lambda_{\tau=1} = 100\pm 17\mu$m, in good agreement with \cite{Gordon:1993}. This is physically interpreted as Sgr B2 (N) being partly embedded in the envelope. The fit shown in Fig. A2 does not use the upper limits as constraints, but the non-detection of Sgr B2 (N) in the Spitzer MIPS 70 micron image shows Sgr B2 (M) and (S) saturated, so that these components and the envelope cannot easily be fitted. The upper limit we quote for Sgr B2 (N) at 70 micron is the flux at the known (from sub-mm) position, in addition to some extended structure, which indicates that the 50 micron flux from \cite{Goldsmith:1992} is an over-estimate, including some flux from extended structure. This would indicate more absorption (and longer $\lambda_{\tau=1}$) may be appropriate, but better high resolution data in the far-infrared range are required to confirm this.

Due to the inter-relationship of parameters $T_d$, $\Omega$ and $\lambda_{\tau=1}$, it is possible to fit the cutoff in the dust SED at high frequencies (infrared, where Sgr B2 (N) is not detected, see Fig. A1) with angular size $\Omega$ as a free parameter, which gives a low temperature ($T\sim 30$ K), but this requires a large angular size $\Omega \sim 500$ arcsec$^2$ which is in disagreement with the measured angular size. In addition, if Sgr B2 (N) had this low temperature, similar to that of the extended envelope, and there was not the absorption), then the 70 micron Spitzer MIPS image would show a clear peak at the Sgr B2 (N) position, in addition to the extended structure. This is not the case, which is further evidence against the low temperature interpretation of the Sgr B2 (N) SED.

We also list in Table A2 the parameters derived from the dust spectrum fits of total hydrogen column density $N_H$, number density $n_H$ and mass $M_H$ for the four components Sgr B2 (N), (M), (S) and envelope. Note that $N_H = N(H I) + 2N(H_2)$ so this includes both molecular and atomic hydrogen. The turnover wavelength $\lambda_{\tau=1}$ is related to total hydrogen column density $N_H$ by $N_H = 1.4 \times 10^{20}$ cm$^{-2}$($\lambda_{\tau=1}/\mu$m)$^2(Z_\odot/Z)$, where $Z/Z_\odot$ is the metallicity, assumed 2 for the Galactic Centre, and $b$ is a dust parameter, assumed 3.4 for components Sgr B2 (N), (M) and (S), with $n_H \gtrsim 10^{-3} \text{cm}^{-3}$ and 1.9 for the envelope with $n_H \lesssim 10^{-6} \text{cm}^{-3}$ from \cite{Gordon:1993} and \cite{Mezger:1990}. The number density $n_H$ and mass $M_H$ are derived using the angular size $\Omega$ to estimate the line-of-sight thickness, and hence volume of the components. These are rough estimates, similar to those derived by \cite{Gordon:1993} from similar fits, but we assume Galactic Centre distance 8.0 kpc.

We note that the three hot cores Sgr B2 (N), (M) and (S) have similar angular size and temperature, but that Sgr B2 (S) has an order of magnitude smaller flux density (both dust and free-free components), column density, number density and mass. The extended envelope is cooler but around an order of magnitude larger in diameter than the cores, or two orders of magnitude in solid angle, and dominates the flux density of both dust and free-free components. The envelope is of much lower number density than the cores, but with much greater mass.

We use these parameters of the Sgr B2 components in Section 5 to interpret the molecular line observations of Section 3.

This paper has been typeset from a TeX/LTEX file prepared by the author.
