We study a model of interacting bosons that occupy the first excited $p$-band states of a two-dimensional optical lattice. In contrast to the much studied single band Bose-Hubbard Hamiltonian, this more complex model allows for non-trivial superfluid phases associated with condensation at non-zero momentum and staggered order of the orbital angular momentum in addition to the superfluid-Mott insulator transition. More specifically, we observe staggered orbital angular momentum order in the Mott phase at commensurate filling and superfluidity at all densities. We also observe a transition between the staggered angular momentum superfluid phase and a striped superfluid, with an alternation of the phase of the superfluid along one direction. The transition between these two phases was observed in a recent experiment, which is then qualitatively well described by our model.

I. INTRODUCTION

Superfluidity has attracted much attention since its discovery in bosonic $^4$He and, later, in fermionic $^3$He [1]. This phenomenon was studied in a wide range of systems ranging from excitons in quantum wells [2] to neutron stars [3]. Interest intensified following the experimental realization of confined ultracold atomic systems, in particular atomic Bose-Einstein condensates (BEC) [4]. Many new possibilities become available when these systems are loaded in the lowest band of optical lattices where they are governed by the (bosonic or fermionic) Hubbard model with highly tunable parameters [5]. After their initial use to explore quantum phase transition between superfluid (SF) and Mott insulator (MI) phases [6] ultracold atomic gases have been used to study mixtures of particles [5,8] and, since then, more exotic pairing phenomena, including Fulde-Ferrell-Larkin-Ovchinnikov [9,10] or breached paired phases [11,12] in unbalanced fermionic systems, or to introduce the concept of counter-superfluidity in MI of boson mixtures [13]. Work on spinor condensates concentrated on the interplay between superfluid behavior and itinerant magnetism, especially through the study of spin-1 bosons [14,15].

More recently, it was proposed to load the atoms in higher bands of the optical lattice in order to study further exotic forms of superfluidity [10]. In a three dimensional cubic lattice, there are three such states that are degenerate and correspond to the different states of orbital angular momentum $l = 1$ ($L^2 = l(l+1) = 2$ in units of $\hbar^2$), whereas the unique ground state corresponds to $l = 0$. Due to the anisotropy used to produce two dimensional square lattices, one of the orbitals has a larger energy than the other two. This reduces the model to only two species (the $p_x$ and $p_y$ states) in the low energy limit. On cubic or square lattices, the hopping parameters from a site to its neighbors are anisotropic and take two different values depending on the hopping direction, parallel or perpendicular to the orbital axis. Isacsson and Girvin [10] studied the limit where the hopping in the transverse directions is totally suppressed. This led them to suggest that in two dimensions their model may develop a peculiar columnar phase ordering where the phases of particles in the $p_x(y)$ states are coherent along the $x(y)$ direction and uncorrelated in the transverse direction.

Bosons in high orbital bands are not in the true ground state. This feature gives rise to the possibility of new states of matter beyond the “no-node” theorem [17] that is obeyed by the conventional BECs of single component bosons. This theorem states that the many-body ground state wavefunctions of bosons under very general conditions are positive-definite. It implies that time-reversal symmetry cannot be spontaneously broken. If the system has rotational symmetry, this theorem constrains the condensate wavefunctions to be rotationally invariant. In other words, conventional BECs are $s$-wave-like whose symmetry property is similar to $s$-wave superconductivity. Recently, unconventional symmetries have been introduced to the single-boson condensates in high orbital bands in optical lattices [18,19], denoted as “unconventional BECs” (UBECs). Their condensate wave functions belong to nontrivial representations of the lattice point group. In other words, they are non-$s$-wave in analogy to unconventional pairing symmetries of superconductivity. Liu and Wu [19] studied analytically the UBECs in the $p$-orbital band with non-zero transverse hopping exhibiting a $p_x \pm ip_y$ type symmetry, and thus breaking time-
reversal symmetry spontaneously with a complex-valued condensate wavefunction. They predicted for densities, $\rho$, larger than two particles per site, the existence of a superfluid phase where the system condenses at nonzero quasi-momentum and which is accompanied by a staggered order of the orbital angular momentum (SAM). Recently, the model was studied using an effective action approach \cite{20} and a similar SF phase with SAM order was predicted even for $\rho = 1$ as well as an antiferromagnetic Mott phase. Its physics was also examined in one dimension \cite{21}. For unconventional symmetries such as the $d$-wave of high $T_c$ cuprates, phase-sensitive detections provide definitive evidence \cite{22, 23}. For the non-$s$-wave UBECs, phase-sensitive detection on condensate symmetries has also been proposed through Raman transition \cite{24}.

Such an exotic SF phase was observed in a recent experiment by Wirth, Ölschläger, and Henmerich \cite{25, 26} in a two-dimensional checkerboard lattice composed of $s$ and $p$-orbitals sites and had been investigated theoretically by Cai et al. \cite{27}. The nearest neighbors of $s$-sites being $p$-sites, an atom cannot go directly from a $p$-site to another as was the case in Liu and Wu’s model \cite{18, 19}. However, the $s$-sites do not introduce phase differences and thus only play the role of a neutral relay between $p$-sites. Introducing a small anisotropy between the $x$ and $y$ axes, a transition between the condensed state at non-zero momentum and a striped phase where there is a phase alternation between different stripes was observed. BECs with unconventional condensate symmetries have also been observed in the solid state exciton-polariton lattice systems \cite{28}.

In this work, we will study the model originally proposed by Liu and Wu \cite{19} with quantum Monte Carlo simulations. To reproduce qualitatively the different phases observed in Hemmerich's group experiment, we will add to the original model an anisotropy term in the form of an energy difference between $p_x$ and $p_y$ orbitals. Finally, in addition to studying the superfluid phase, we will also focus on the insulating phases that arise in such systems for strong enough interactions and integer densities. In section II of this article, we will introduce and discuss the model, in section III we will show that it can be mapped on a bosonic spin-1/2 model and establish the correspondence between the phases observed. In section IV, we will present the results of our simulations and conclude in section V.

II. THE $p$-ORBITAL MODEL

We will study the model introduced in \cite{18, 19} for the two-dimensional square lattice and two-species ("spin-$\frac{1}{2}$") case. The system is then governed by the Hamiltonian,

\[
H = +t_{\parallel} \sum_{\mathbf{r}} \left( p_{x,\mathbf{r}}^\dagger p_{x,\mathbf{r}+\mathbf{e}_x} + p_{y,\mathbf{r}}^\dagger p_{y,\mathbf{r}+\mathbf{e}_y} + h.c. \right) - t_{\perp} \sum_{\mathbf{r}} \left( p_{x,\mathbf{r}}^\dagger p_{x,\mathbf{r}+\mathbf{e}_y} + p_{y,\mathbf{r}}^\dagger p_{y,\mathbf{r}+\mathbf{e}_y} + h.c. \right) + \frac{U}{2} \sum_{\mathbf{r}} \left( n_{x,\mathbf{r}}^2 - \frac{L_z^2}{3} \right) + \Delta \sum_{\mathbf{r}} (n_{x,\mathbf{r}} - n_{y,\mathbf{r}}),
\]

where $p_{x,y,\mathbf{r}}$ is the destruction operator of a particle located on site $\mathbf{r} = (r_x, r_y)$ of an $L \times L$ square lattice in the $p_x(p_y)$ state; $\mathbf{e}_x$ and $\mathbf{e}_y$ are the primitive vectors of the square lattice. The number operators are $n_{x,y,\mathbf{r}} = p_{x,y,\mathbf{r}}^\dagger p_{x,y,\mathbf{r}}$, and $n_{x} = n_{x,\mathbf{r}} + n_{y,\mathbf{r}}$, and $L_z$ is the on-site orbital angular momentum operator defined as

\[
L_{z,\mathbf{r}} = \hat{L}_{x,\mathbf{r}}^2 - i (p_{x,\mathbf{r}}^\dagger p_{y,\mathbf{r}} - p_{y,\mathbf{r}}^\dagger p_{x,\mathbf{r}}),
\]

We remark that $\hat{L}_{z,\mathbf{r}}$ is not diagonal in this basis and contains terms that transform two particles of one species into two particles of the other species.

Since the overlap of $p$-orbitals on neighboring sites is different in the directions parallel or perpendicular to their spatial orientation, there are two different hopping parameters. $t_{\perp}$ is typically smaller than $t_{\parallel}$ (Fig. 1). Moreover, due to the phase difference between the two parts of the $p$-orbitals, the two hopping terms have different signs (Eq. (II)), being positive in the parallel direction ($+t_{\parallel}$) whereas the perpendicular hopping term maintains the conventional negative sign ($-t_{\perp}$). We will concentrate on the case where $t_{\perp} = t_{\parallel} = t$, but also retain the sign difference. The parameter $t$ sets the energy scale. The interaction part of the Hamiltonian (Eq. (II)) includes a conventional on-site repulsion (the $n_{x}^2$ term) and a term that maximizes the on-site angular momentum (the $L_{z,\mathbf{r}}^2$ term). This is essentially the

\[
\begin{array}{c}
\text{FIG. 1: Hopping parameters on the square lattice for } p_x \text{ and } p_y \text{ orbitals. Because } p_{x(y)} \text{ orbitals are parity odd, the overlap of orbitals changes sign depending on the direction. Along the parallel direction (} x \text{ for } p_x \text{ orbitals, } y \text{ for } p_y \text{ orbitals), the overlap is negative, which gives a positive } +t_{\parallel} \text{ hopping parameter. On the other hand, along the perpendicular direction, there is a conventional negative hopping parameter } -t_{\perp}. \end{array}
\]
physics of second Hund’s rule applied to the bosonic orbital system: complex orbitals are spatially more extended to save repulsive interactions. The last term in the Hamiltonian, Eq. (1) corresponds to a tunable extended to save repulsive interactions. The last term.

In the non interacting limit, the energy dispersion for \( p_x \) particles \( \epsilon(k) = 2\cos(k_x) \) takes the form \( \epsilon(k) = 2\cos(k_x) - \cos(k_y) \) where \( k = (k_x, k_y) \). Since the energy minima appear at \( k = (\pi, 0) \) for the \( p_x \) particles and at \( k = (0, \pi) \) for the \( p_y \) particles, it is expected for the system to condense at non zero momentum.

Finally the \( \Delta \) term in Eq. (11) should suppress this kind of order since it requires having the same number of \( p_x \) and \( p_y \) particles by increasing the density of \( p_y \) particles. If the system remains superfluid when it is composed mostly of \( p_y \) particles, the phase will alternate between sites along the \( y \) direction and will be coherent in the \( x \) direction, thus forming stripes along the \( x \) axis. We will call this phase a striped superfluid (see Fig. 3).

### III. MAPPING ON A SPIN 1/2 MODEL

The positive parallel hopping term in Eq. (11) generates a sign problem for Quantum Monte Carlo simulations. (In this work we use the Stochastic Green Function algorithm \[29, 30\]). However, the Hamiltonian can be mapped onto a spin–1/2 model free of this problem \[31, 32\]. We define the spin 1/2 bosonic operators

\[
\begin{align*}
    b^\dagger_{\uparrow, x} &= i(-1)^x p_{\uparrow, x} & b^\dagger_{\downarrow, x} &= (-1)^y p_{\downarrow, x} \\
\end{align*}
\]

This transformation gives a direct equivalence between densities of \( \uparrow (\downarrow) \) and \( p_x (p_y) \) particles. Then, following a Schwinger boson approach \[33\], the corresponding spin 1/2 operators are defined:

\[
S_{\uparrow, x} = (n_{\uparrow, x} - n_{\downarrow, x})/2, \quad S_{\downarrow, x} = b^\dagger_{\uparrow, x} b_{\downarrow, x}, \quad S_{\downarrow, x} = b^\dagger_{\downarrow, x} b_{\uparrow, x}.
\]

With these definitions, the model is rewritten, up to some constants, as

\[
H_{1/2} = -t \sum_x \sum_{\sigma=\uparrow, \downarrow} \sum_{\alpha=x,y} (b^\dagger_{\sigma, x} b_{\sigma, x+\alpha} + h.c.) + \sum_x \left( U n_x (n_x - 1) - \frac{2U}{3} S_{z, x}^2 + 2\Delta S_{z, x} \right)
\]

where \( S_{z, x} = (S_{\uparrow, x} + S_{\downarrow, x})/2 \) and plays a rôle similar to the \( L_{z, x} \) operator in the original model.

Up to the external field term along the \( z \)-direction, this is the model that was studied in \[31, 32\] with \( U_0 = U \) and \( U_2 = -U/3 \) for the values of the parameters used in these articles. For \( \Delta = 0 \), it was shown that the system is always ferromagnetic at low temperature. On a given site, the absolute value of the projection of the
spin along the x axis is maximized due to the negative \( S_{x,r}^2 \) term. The hopping of the particles then creates an effective ferromagnetic coupling between spins located on different sites. This ferromagnetic order is of the Ising class because of the anisotropy introduced by the \( S_{x,r}^2 \) term. It is measured by calculating the spin-spin correlation function along the x axis, related to the correlation of angular momenta \( C_z(R) \) in the original model \((R = (R_x, R_y))\),

\[
C_z(R) = \langle L_{z,r}L_{z,r+R} \rangle = 4(-1)^{R_x+R_y} \langle S_{x,r}S_{x,r+R} \rangle \tag{5}
\]

That is, the observed ferromagnetism in the spin−1/2 model corresponds to the staggered angular momentum predicted in the p-band model.

Although it always adopts ferromagnetic behavior at \( \Delta = 0 \), the system can be in different incompressible Mott phases, at integer densities and large enough interaction \( U \), or in a superfluid phase, for non integer densities and for integer densities at low enough interaction \( U \). A constant value, at long distance, of the one particle Green functions \( G_\sigma(R) = \langle b_{\sigma,r}^\dagger b_{\sigma,r+R} \rangle \) shows that the particles have condensed and that the system is superfluid. In terms of p-band particles, the Green functions \( G_x(y)(R) = \langle p_{x(y),r}p_{x(y),r+R} \rangle \) have the following expressions,

\[
G_x(R) = (-1)^{R_x}G_y(R), \quad G_y(R) = (-1)^{R_y}G_x(R) \tag{6}
\]

That is, a superfluid/BEC phase for spin 1/2 particles translates directly into the BEC at non zero momentum phase for the p-band particles, because of the real space phase factors \((-1)^{R_x}\) and \((-1)^{R_y}\).

The same correspondence holds for the Fourier transforms of these functions, namely the spin 1/2 magnetic structure factor at \( k = (0,0) \) becoming an angular momentum structure factor at \( k = (\pi, \pi) \) (we will call this quantity \( S_{\text{SAM}} \) in the following) and the density of condensed spin 1/2 particles at \( k = (0,0) \) becoming the density of condensed \( \rho_x \) and \( \rho_y \) particles at \( k = (\pi, 0) \) and \( k = (0, \pi) \), respectively, which will be denoted \( \rho_{cx} \) and \( \rho_{cy} \) in the following.

Finally, in the spin−1/2 model, it is possible to measure the superfluid density \( \rho_s \) through the fluctuations of total winding numbers \( \langle r \rangle \)

\[
\rho_s = \frac{\langle W_x^2 + W_y^2 \rangle}{4\beta t} \tag{7}
\]

At zero temperature, the superfluid density \( \rho_s \) and the condensed densities \( \rho_{cx} \) and \( \rho_{cy} \) are generally non-zero simultaneously so we will use \( \rho_s \) to determine if we are in the condensed phase for both models.

IV. SIMULATION RESULTS

Quantum Monte Carlo simulations using the SGF algorithm \( 29, 30 \) allow us to study the spin−1/2 model at finite temperature for \( L \times L \) lattices up to \( L = 10 \) and inverse temperature up to \( \beta t = 80 \). The difficulty of the simulations is caused by the \( S_{x,r}^2 \) interaction term which changes the spin projection of the particles. The simulations are performed at low temperatures in order to obtain the behavior of the ground states. We will concentrate on \( \Delta \neq 0 \).

A. Phase diagrams

We expect Mott phases to appear for large enough interactions and integer densities \( \rho \). To determine the extent of these phases in the \( (t/U, \mu/U) \) plane for a given value of \( \Delta \) we calculate the energy \( E(N) \) at low temperature for \( N = \rho L^2 \), \( N + 1 \), and \( N - 1 \) particles. We then determine the boundaries of the Mott lobe as \( \mu_+ = E(N+1) - E(N) \) and \( \mu_- = E(N) - E(N-1) \), and \( \mu_+ \) is larger than \( \mu_- \) by a finite value, the charge gap. As expected, we find Mott phases occur for integer densities \( \rho = 1 \) and \( \rho = 2 \). (We did not go beyond \( \rho = 2 \)). We observe that the boundaries of the different phases are not changed much when \( \Delta \) is varied (Fig. 4). Since the energy is a local quantity which is not very sensitive to system size, the boundaries of the Mott lobes are little changed with system size as seen in Fig. 5. We will detail below the nature of these three phases for different densities.

B. \( \rho = 1 \) case

In Fig. 6 we present the dependence of the particles, superfluid, and condensate densities and the angular momentum structure factor on the interaction \( U \) at fixed...
and $\Delta = 0$. 

$\rho$ at low interaction to a Mott phase as density condensed phase. Increasing interaction $U$ is increased, $\rho$ behavior. There is a correlation between $\rho$ for non zero $\Delta$, that $S$ which can be understood by noting that requires a superposition of $p$ superfluid density decreases monotonically with $U$ along the $\Delta = 0$, the larger coupling of the Heisenberg model is an effective anisotropic spin 1/2 Heisenberg model. For this Mott phase the model can then be mapped onto the system is driven into an incompressible Mott phase $\rho$ is possible only when double occupancy is suppressed at large $U$. In this Mott phase the model can then be mapped onto an effective anisotropic spin 1/2 Heisenberg model. For $\Delta = 0$, the larger coupling of the Heisenberg model is along the $x$ axis and is equal to $J_z = -9t^2/U$ which leads to ferromagnetic order. This is SAM order in terms of $p$-band bosons $\frac{13}{13}, \frac{12}{12}$. The $\Delta$ term acts as an external magnetic field along the $z$ axis and tends to destroy the ferromagnetic/SAM order. In Fig. 6, the Mott phase is composed only of $p_y$ particles ($\rho_y \approx 1$) as $\Delta$ is large enough to overcome the ordering of effective spins along the $x$-axis. There is, then, no SAM order in the Mott phase in this case. However, the Mott phase shows a SAM order for small enough values of $\Delta$ (see Fig. 7, bottom).

Returning to the low interaction regime, there are two different superfluid phases observed in Fig. 6. At low interaction $U$, the system is well described as a collection of free particles and, since the $\Delta$ term lowers the energy of $p_y$ states, the particles condense in this state. $L_z$ is then on average zero on each site and no SAM is observed. The $p_y$ bosons form a condensate and the phase is a striped superfluid because $\rho_{cy}$ is nonzero. For intermediate interaction, we observe a SAM superfluid where $\rho_{cx}, \rho_{cy}$ and $S_{SAM}$ are non zero at the same time. For such moderate $U$, the interaction is not large enough to block particles in a Mott phase but, to lower the energy, the system adopts states that have non zero $L_z$ on a site and the hopping terms lock the relative phases into an SAM order. As in the Mott case, the SAM order will disappear if the system is composed of only $p_y$ particles due to a large value of $\Delta$ (see Fig. 7, bottom).

Finally, using different cuts in the phase diagram at fixed $\Delta$ or $U$, similar to Figs. 6 and 7, we map the phase diagram presented in Fig. 8 for $\rho = 1$. We observe that for the range of values we studied, the SAM order completely disappears for $\Delta > 1$ and the system is in a
FIG. 8: (Color online) Phase diagram for \( \rho = 1 \) as a function of \( U/t \) and \( \Delta/t \). There are four different phases: a Mott phase, a Mott phase with staggered orbital momentum (SAM) order, a superfluid phase with SAM order and a striped superfluid. Mott phase for \( U > 25 \).

C. \( \rho = 2 \) case

We performed the same analysis for the \( \rho = 2 \) case and found similar results (see Figs. 9, 10, and 11). However, the SAM is much more robust, as it persists up to \( \Delta = 4 \). This can be understood by recalling that the \( J_z^2 \) term scales as the square of the density. Thus the associated SAM coupling of the angular momentum should grow rapidly with the density and the stripe phase is therefore more difficult to observe.

D. Non integer densities

At non integer densities, the system is of course always superfluid. As at commensurate fillings \( \rho = 1 \) and \( \rho = 2 \), we observe a transition between the SAM superfluid phase and the stripe superfluid as \( \Delta \) is increased. The limiting value of \( \Delta \) grows with increasing density, a trend already evident in comparing results for the two integer
fillings (Fig. 12). The value of $\Delta$ at which the SAM disappears corresponds to the system being populated almost entirely by $p_y$ particles. We observe the SAM order for any density, which is in contradistinction with the results from [18] where the SAM phase was expected to appear only for $\rho = 1$ Mott phase. Contrary to what was expected, [18, 19] our QMC simulations indicate that the SAM superfluid phase can be observed for any density, and not just for densities larger than two, although it becomes more robust as the density is increased. The presence of the SAM order in the $\rho = 1$ Mott can be understood with an analysis in terms of an effective Heisenberg model.

Despite its differences with the experiment of Hemmerich and co-workers (namely the absence of the s-wave sites), the simple model studied here gives a good qualitative description of the results. It reproduces the two observed superfluid phases, the SAM and stripe superfluids, with the same condensations at non zero momenta. It also reproduces the transition between these two exotic superfluids driven by the energy difference $\Delta$ between the two species. Moreover, our results suggest that in a system with stronger repulsive interaction, a similar phase transition between a SAM and a non-SAM phase could be observed in a Mott insulating phase.

Here, we focused exclusively on the isotropic case, $t_{\perp} = t_{\parallel}$, although an experimental realisation would have anisotropies, $t_{\perp} \neq t_{\parallel}$. We have done some preliminary simulations (not shown here) for $t_{\perp}$ and $t_{\parallel}$ values that are not very different. These indicate that the physics remains qualitatively the same. The case of extreme anisotropy, $t_{\perp}/t_{\parallel} \ll 1$ and even $t_{\perp} = 0$ does differ [16] and merits special attention.

V. CONCLUSION

We studied a model for $p$-band superfluidity [18, 19] using exact quantum Monte Carlo simulations. We found that the phase diagram of the model is composed of a striped superfluid, a superfluid with simultaneous staggered angular momentum order (SAM), a SAM Mott and a Mott phase. Contrary to what was expected, [18, 19] our QMC simulations indicate that the SAM superfluid phase can be observed for any density, and not just for densities larger than two, although it becomes more robust as the density is increased. The presence of the SAM order in the $\rho = 1$ Mott can be understood with an analysis in terms of an effective Heisenberg model.

Despite its differences with the experiment of Hemmerich and co-workers (namely the absence of the s-wave sites), the simple model studied here gives a good qualitative description of the results. It reproduces the two observed superfluid phases, the SAM and stripe superfluids, with the same condensations at non zero momenta. It also reproduces the transition between these two exotic superfluids driven by the energy difference $\Delta$ between the two species. Moreover, our results suggest that in a system with stronger repulsive interaction, a similar phase transition between a SAM and a non-SAM phase could be observed in a Mott insulating phase.

Here, we focused exclusively on the isotropic case, $t_{\perp} = t_{\parallel}$, although an experimental realisation would have anisotropies, $t_{\perp} \neq t_{\parallel}$. We have done some preliminary simulations (not shown here) for $t_{\perp}$ and $t_{\parallel}$ values that are not very different. These indicate that the physics remains qualitatively the same. The case of extreme anisotropy, $t_{\perp}/t_{\parallel} \ll 1$ and even $t_{\perp} = 0$ does differ [16] and merits special attention.
