Stretched String with Self-Interaction at High Resolution: Spatial Sizes and Saturation

Yachao Qian and Ismail Zahed

Department of Physics and Astronomy, Stony Brook University, Stony Brook, NY 11794-3800.

(Dated: November 14, 2014)

We model the (holographic) QCD Pomeron as a long and stretched (fixed impact parameter) transverse quantum string in flat $D_\perp = 3$ dimensions. After discretizing the string in $N$ string bits, we analyze its length, mass and spatial distribution for large $N$ or low-$x$ ($x = 1/N$), and away from its Hagedorn point. The string bit distribution shows sizable asymmetries in the transverse plane that may translate to azimuthal asymmetries in primordial particle production in the Pomeron kinematics, and the flow moments in minimum bias $pp$ and $pA$ events. At moderately low-$x$ and relatively small string self-interactions $g_s \approx \alpha_s$ (the gauge coupling), a pre-saturation phase is identified whereby the string transverse area undergoes a first order transition from a large diffusive growth to a small fixed size area set by few string lengths $l_s$. This phase amounts to a saturation of the cross section within the Froissart bound. For lower values of $x$ the transverse string bit density is shown to increase as $1/x$ before saturating at the Bekenstein bound of one bit per Planck area. The Planck scale is identified as $l_P \approx \alpha_s^{2/3} l_s$ through holography.

I. INTRODUCTION

Hadron-hadron collisions at high energies but soft momentum transfer are dominated by soft Pomeron exchange, an effective $0^{++}$ exchange corresponding to the highest Regge trajectory with intercept $\alpha_P(0) - 1 \approx 0.08$ \cite{1}. Reggeon exchanges with spin-isospin quantum numbers have smaller intercepts and are therefore sub-leading \cite{2,3}. The growth of the total hadron-hadron cross-section with the rapidity interval $\chi = \ln(s/s_0)$ is described phenomenologically in the context of Reggeon field theory. In QCD the re-summation of the soft collinear Bremmstralung contributions through the BFKL ladders yield a hard Pomeron with a perturbatively small intercept and zero slope \cite{4,5,6,7,8}.

Soft Pomeron are altogether non-perturbative. Duality arguments put forth by Veneziano \cite{9} suggest that the soft Pomeron is a closed string exchange in the $t$-channel, with a string world-sheet made of planar diagrams like fish-nets \cite{10}. The quantum theory of planar diagrams in the double limit of strong coupling and large number of colors is tractable in supersymmetric theories using the holographic principle \cite{11}. Many descriptions of the soft Pomeron in holographic duals to QCD have been suggested recently without supersymmetry \cite{12,13,14}. A simple version is a stringy exchange in AdS$_5$ with a wall with $D_\perp = 3$ dimensions, that reproduces a number of features of diffractive scattering, production and low-$x$ DIS. Throughout and for simplicity, the curvature of AdS$_5$ will be ignored.

The Pomeron as a string exchange in holography can be thought as a chain of closed but confined gluons, some sort of non-perturbative Weizacker-Williams field tying two colorless dipoles separated by a large rapidity interval $\chi$. In this spirit, lepton on proton scattering in DIS at low-$x$ can be described through a holographic string exchange with the identification $\chi \approx \ln(1/x)$. In the proton rest frame, the leptonic dipole of size $1/Q$ acts as a small probe dipole scattering off the larger dipole composing the proton at a fixed impact parameter $b$. DIS experiments are always averaged over this impact parameter when measuring gluonic densities in structure functions. However, the dominant contribution in the averaging stems from large $b$ \cite{27,28,29}. More exclusive experiments could be done in future electron-Ion-Colliders to unravel the impact parameter dependence at low-$x$ as well.

Low-$x$ physics translates to a large $N = 1/x$ resolution of the holographic string as we detail below. This is achieved for long strings by discretizing the transverse Polyakov scalar action in $N$ string bits and ignoring initially the stringy interactions (free string). String bits have been identified with wee (gluonic) partons by Thorn \cite{32,33}. The slow logarithmic growth of the free string transverse area translates to an anomalously large transverse string bit density at low-$x$. Repulsive string interactions can cause the transverse density to conform with the maximum Bekenstein bound for a black-hole as argued by Susskind for wee gravitons \cite{16,34,35}. However, such a growth appears to be at odd with the Froissart bound \cite{36}.

A high string bit density at low-$x$ points towards a liquid of string bits, a priori resolving the string. However, the underlying presence of the string is still paramount to maintain the (Gribov) diffusion of the string bits in the transverse plane. Recall that the diffusion constant $D = l_s^2/2$ is dimensionfull and ties with the squared string length. Also, a highly resolved string provides an optimal description of low-$x$ saturation in QCD as wee partons reaching the Bekenstein bound \cite{37,38}. In this work we will show that the bound is reached in two stages. First a dilute pre-saturation stage where the string transverse area undergoes a first order transition from a large diffusive growth to a small but fixed size set by the string scale for relatively weak string self-interactions. The cross section freezes below the Froissart bound \cite{36}. Second a dense saturation stage at very low-$x$ whereby the transverse string bit
density saturates the Bekenstein bound of one bit per transverse Planck area.

Our pre-saturation condition is consistent with the saturation condition following from the stringy dipole-dipole cross section analysis derived by Stoffers and one of us [27–29]. In some ways, our stringy description of saturation can be regarded as the dual of the weak coupling description of gluon saturation in QCD based on the color glass condensate [42] in the impact parameter space, where the string provides a natural enforcement of Gribov transverse diffusion. The exponential rise of the string density of states with its mass provides the most efficient way of scrambling information and reaching the Bekenstein bound and thus the saturation point as we will show below.

In section 2 we detail the discretized version of the transverse scalar string in flat $D_{\perp}$ dimensions. We analyze numerically its geometrical distributions for different resolutions. Self-string interactions both attractive and repulsive are introduced and discussed in the mean-field approximation in section 3. Using a Gaussian variational approach we re-assess the geometrical properties of the transverse string at various resolution in section 4. Detailed numerical sampling of the string using the variational analysis are given in section 5. At low-x a pre-saturation stage with fixed and small string geometry, followed by saturation when the Bekenstein bound is reached are discussed in section 6. Details about the azimuthal deformation of the string distribution are given in section 7 in terms of standard flow and small string geometry, followed by saturation when the Bekenstein bound is reached are discussed in section 6. Details about the azimuthal deformation of the string distribution are given in section 7 in terms of standard flow moments in the diffusive and pre-saturation phases. Our conclusions are in section 8.

II. DISCRETIZED FREE TRANSVERSE STRING

Scattering of dipoles in the pomeron kinematics with a large rapidity interval $\chi = \ln(s/s_0)$ and fixed impact parameter $b$ is dominated by a closed t-channel string exchange. In leading order in $\chi$, the exchange amplitude can be shown to be that of a free transverse string at fixed Unruh temperature $T = a/2\pi$ with the mean world-sheet acceleration $a = \chi/b$ [26–29, 43]. The free transverse string with fixed end-points in $D_{\perp}$ dimensions is characterized by

\[ S_{\perp} = \frac{\sigma_T}{2} \int d\tau \int_0^\pi d\sigma \left[ (\dot{x}_\perp)^2 + (x'_\perp)^2 \right] \]

with the end-point condition

\[ x^i_\perp(\sigma = 0, \tau) = 0 \quad x^i_\perp(\sigma = \pi, \tau) = b^i \]

The string tension is $\sigma_T = 1/(2\pi \alpha')$ with $\alpha' = l_s^2$. For simplicity, we will set $2l_s \equiv 1$ throughout and restore it by inspection when needed. The purpose of the present work is to show how the concept of saturation at low-x emerges from the string description and identify its key parameters in QCD through holography. We will also study the general geometrical structure of the transverse string, in particular its spatial size and deformation in the cold or pomeron regime both for a free and interacting string. Initial geometrical string deformations maybe the source of large prompt azimuthal deformations in the inelastic channels and for high multiplicity events.

The transverse free string (2.0.1) can be thought as a collection of $N$ string bits connected by identical strings [32, 33] and discretized as follows

\[ L_{\perp} = \frac{1}{N} \sum_{k=0}^{N} \left( \dot{x}_\perp^i(k) \right)^2 - \frac{1}{N} \sum_{k=1}^{N} \left( \frac{x^i(k) - x^i(k-1)}{\frac{\pi}{N}} \right)^2 \]

with $S_{\perp} = \int d\tau L_{\perp}$. For $N \to \infty$ the (2.0.1) is recovered. Using the mode decomposition for the amplitudes $x^i_\perp$

\[ x^i_\perp(k, \tau) = \frac{b^i}{N} k + \frac{1}{N} \sum_{n=1}^{N-1} X^i_n(\tau) \sin \left( \frac{n k}{N} \pi \right) \quad (k = 0, 1, \cdots, N) \]

and their conjugate momenta

\[ p^i_\perp(k, \tau) = \frac{\partial L}{\partial \dot{x}_\perp^i} = \frac{2}{N} \dot{x}_\perp^i = \frac{2}{N} \sum_{n=1}^{N-1} X'_n(\tau) \sin \left( \frac{n k}{N} \pi \right) \equiv \frac{2}{N} \sum_{n=1}^{N-1} P^i_n(\tau) \sin \left( \frac{n k}{N} \pi \right) \]

allow us to write the Hamiltonian
\[ H_\perp = \frac{N}{4} \sum_{k=0}^{N} (p_k^i)^2 + \frac{1}{N} \sum_{k=1}^{N} \left( \frac{x_k^i - x_{k-1}^i}{\pi N} \right)^2 \]
\[ = \frac{1}{2} \sum_{n=1}^{N-1} (P_n^i(\tau) P_n^i(\tau) + \Omega_n^2 X_n^i(\tau) X_n^i(\tau)) + \frac{b^2}{\pi^2} \]  
(2.0.6)

with free harmonic oscillators of frequencies

\[ \Omega_n = \frac{2N}{\pi} \sin \left( \frac{n\pi}{2N} \right) \]  
(2.0.7)

Each oscillator in \( H_\perp \) carries a small mass \( m_N = 2/N \) and a large compressibility \( k_N = 4/(\pi^2 m_N) \). The ground state of this dangling \( N \)-string bit Hamiltonian is a product of Gaussians

\[ \Psi[X] = \prod_{n,i} \Psi(X_n^i) = \prod_{n,i} \left( \frac{\Omega_n}{\pi} \right)^{\frac{1}{4}} \exp \left[ -\frac{\Omega_n}{2} (X_n^i)^2 \right] \]  
(2.0.8)

leading to the ground state energy

\[ \langle H_\perp \rangle = \frac{D_\perp}{2} \sum_{n=1}^{N-1} \Omega_n + \frac{b^2}{\pi^2} = \frac{D_\perp}{2} \frac{N}{\pi} \left[ \cot \left( \frac{\pi}{4N} \right) - 1 \right] + \frac{b^2}{\pi^2} \]  
(2.0.9)

The string transverse squared size is

\[ R_\perp^2 = \frac{1}{N} \sum_{k=0}^{N} \left( \frac{x_k^i - b_k^i}{N} \right)^2 = \frac{D_\perp}{4} \sum_{n=1}^{N-1} \frac{1}{\Omega_n} \]  
while its transverse squared mass is

\[ M_\perp^2 = \frac{1}{2} \langle H_\perp \rangle = \frac{D_\perp}{4} \sum_{n=1}^{N-1} \Omega_n + \frac{b^2}{2\pi^2} = \frac{D_\perp}{4} \frac{N}{\pi} \left[ \cot \left( \frac{\pi}{4N} \right) - 1 \right] + \frac{b^2}{2\pi^2} \]  
(2.0.10)

We note that back to the continuum \( \Omega_n \to n \) with the ground state wave functions

\[ \Psi(X_n^i) = \left( \frac{n}{\pi} \right)^\frac{1}{4} \exp \left[ -\frac{n}{2} (X_n^i)^2 \right] \]  
(2.0.11)

so that

\[ \langle H_\perp \rangle \approx \frac{2D_\perp}{\pi^2} N^2 + \frac{b^2}{\pi^2} \]  
(2.0.12)

The transverse squared radius of the string diverges logarithmically

\[ R_\perp^2 \approx \frac{D_\perp}{4} \ln(N) \]  
(2.0.13)

while its effective squared mass diverges quadratically

\[ M_\perp^2 \approx \frac{D_\perp}{\pi^2} N^2 + \frac{b^2}{2\pi^2} \]  
(2.0.14)

with the number \( N \) of string bits.
A simple interpretation of \( N \) in relation to the holographic Pomeron follows from the diffusive equation for the tachyonic mode of the closed string exchange in \([27]\),

\[
\left( \partial_t - \frac{D_{12}}{12} \right) K = \frac{\alpha'}{2} \Delta_1^2 K \equiv \frac{1}{8} \Delta_1^2 K
\]

where \( K \) is the quantum propagator for long closed strings in flat \( D_{12} + 2 \) space. The last equality follows after setting \( 2l_s = 1 \) in our current conventions. The curvature of AdS$_5$ causes the leading Pomeron intercept \( D_{12}/12 \rightarrow D_{12}(\lambda)/12 \) in leading order in \( \lambda = g_{YM}^2 N_c \) with \( 2 < D_{12}(\lambda) < 3 \). Thus the transverse diffusive size of the Pomeron is

\[
R_{\perp}^2 = \frac{D_{12}}{12} \chi = \frac{D_{12}}{4} \ln \left( \frac{Q^2}{s_0} \left( \frac{1}{x} - 1 \right) \right)
\]

where the last equality uses the DIS kinematics \([27]\). Thus, the identification

\[
R_{\perp}^2 \approx \frac{D_{12}}{4} \ln \left( \frac{1}{x} \right)
\]

for small \( x \), which leads to

\[
N \equiv \frac{1}{x}
\]

as the string resolution as suggested earlier.

In its ground state, each of the discretized string bit coordinates \( X_i \) is normally distributed with probability \( |\Psi(X_i)|^2 \). This gives rise to a random walk of the string bits along the chain in the transverse direction with fixed end-points. This is also true for the continuum. In Fig. 1 and Fig. 2 we show the string shape for a fixed distance \( b = 5 \) for two distinct resolutions \( N = 10 \) and \( N = 50 \) respectively. The left figure is the string projected in the transverse plane, while the right figure is the string in \( D_{12} = 3 \) dimensions. Fig. 3 (left) show the string bits in the transverse plane for an ensemble of 200 strings at a resolution of \( N = 10 \) with fixed \( b = 5 \). Fig. 3 (right) shows the same for 40 strings at a higher resolution \( N = 50 \).

\[\text{FIG. 1: Free transverse string shape at a resolution } x = 1/10 \text{ and } b = 5.\]

**III. SELF-INTERACTING STRING IN THE MEAN-FIELD APPROXIMATION**

Attractive string self-interaction will cause the string to shrink transversely, while repulsive self-interactions will cause the transverse string to grow outward, in a way pushing the string bits out. While string bits are held by confinement which is harmonic in our discretized case, self-string interactions are not well-known. We now postulate that for a sufficiently high resolution or large \( N \) we may average the inter-bit interactions in the string using two-body self-interactions.
\[ V = -\frac{g^2}{2} \sum_{k \neq k'} \int \frac{d^{D-1+1}}{(2\pi)^{D-1+1}} \frac{M(\vec{x}_k)M(\vec{y}_k)}{p^2 + m^2} \exp(i\vec{p} \cdot (\vec{x}_k - \vec{y}_k)) \]  

(3.0.1)

where \( M(\vec{x}_k) \) is the mass of the discrete point at \( \vec{x}_k \). Here \( m \) is a finite mass in units of the string length that characterizes the range of the interaction. Most of our numerical analyses to follow will be for \( m = 0 \). Results at finite \( m \) may be mapped on \( m = 0 \) through a pertinent re-scaling of the bare coupling \( g \). Note that the static interaction involves the virtual exchange in \( D_{\perp} + 1 \) as the holographic set up is in \( D_{\perp} + 2 \). For simplicity, the curvature of AdS\(_5\) is ignored.

In holographic QCD \( m \) is typically the mass of the graviton in bulk which is dual to the glueball mass on the boundary. In the large number of colors limit, the value of \( m \) is large. However, for a finite number of colors and flavors mixing between the glueballs and the flavor scalars lead to a much lighter \( m \) [44–46]. Also, in a dense but cold gluon medium the glueball mass maybe lighter. In our case we will consider \( m \) a parameter that could be re-absorbed by redefining \( g \). Throughout we will discuss in detail the attractive self-interactions or \( g^2 > 0 \). The repulsive case and results will only be quoted. Note that our analysis of the string ground state is quantum so that self-interactions do not result in a string collapse thanks to the quantum uncertainty principle.

For large \( N \), the bit coordinates \( x_k \) and \( x_{k'} \) are approximately independent. They are normally distributed with a probability distribution

\[ \rho(\vec{x}_k) = \left( \frac{1}{\Sigma_k \sqrt{2\pi}} \right)^{D_{\perp}} \exp\left( -\frac{(\vec{x}_k - \vec{b}_k/N)^2}{2\Sigma_k^2} \right) \]  

(3.0.2)

The squared variance is

\[ \Sigma_k^2 = \sum_{n=1}^{N-1} \frac{\sin^2 \left( \frac{\omega_n \pi}{2\omega_n} \right)}{2\omega_n} \approx \sum_{n=1}^{N-1} \frac{1}{4\omega_n} = \frac{R_{\perp}^2}{D_{\perp}} \]  

(3.0.3)
We note that the normal frequencies \( \omega_n \) differ from the free frequencies \( \Omega_n \). They are defined variationally below. \( (3.0.1) \) is a highly simplified two-body interaction as higher-order many-body interactions are also possible. We just note that \( g = 1/N_c \) justifying the dominance of the two-body interactions.

Using \( (3.0.2) \) we may define the bit mass distribution on the string in the mean-field type approximation as

\[
M(\bar{x}_k) \approx \frac{M_\perp}{N + 1} \rho(\bar{x}_k)
\]

Inserting \( (3.0.2-3.0.4) \) into \( (3.0.1) \) yield

\[
V = -\frac{g^2}{2} \sum_{k \neq k'} \left( \frac{M_\perp}{N + 1} \right)^2 \int d^{D_\perp + 1} p \left( \frac{2\pi}{D_\perp + 1} \right)^{D_\perp + 1} \rho(\bar{x}_k) \rho(\bar{y}_k') \frac{e^{i\bar{p} \cdot (\bar{x}_k - \bar{y}_k')}}{p^2 + m^2}
\]

In the large \( N \) limit, we may average \( (3.0.7) \) over \( x_k \) and \( y_k \) to obtain in the mean-field approximation

\[
\begin{align*}
\nabla &= -\frac{g^2}{2} \sum_{k \neq k'} \left( \frac{M_\perp}{N + 1} \right)^2 \int d^{D_\perp} x_k \int d^{D_\perp} y_k \left( \frac{2\pi}{D_\perp + 1} \right)^{D_\perp + 1} \rho(\bar{x}_k) \rho(\bar{y}_k') \frac{e^{i\bar{p} \cdot (\bar{x}_k - \bar{y}_k')}}{p^2 + m^2} \\
&= -\frac{g^2}{2} \sum_{k \neq k'} \left( \frac{M_\perp}{N + 1} \right)^2 \int d^{D_\perp + 1} p \left( \frac{2\pi}{D_\perp + 1} \right)^{D_\perp + 1} \frac{1}{p^2 + m^2} \exp \left[ -\frac{p^2}{2} \left( \Sigma_k + \Sigma_{k'} \right) + i\bar{p} \cdot (k - k') \right]
\end{align*}
\]

Thus

\[
\begin{align*}
\nabla &\approx -\frac{g^2}{2} M_\perp \int d^{D_\perp + 1} p \left( \frac{2\pi}{D_\perp + 1} \right)^{D_\perp + 1} \frac{1}{p^2 + m^2} \int_0^1 dk \int_0^1 dk' \exp \left[ -\frac{p^2 R^2}{D_\perp} + i\bar{p} \cdot \bar{b}(k - k') \right] \\
&= -\frac{g^2}{2} M_\perp \int d^{D_\perp + 1} p \left( \frac{2\pi}{D_\perp + 1} \right)^{D_\perp + 1} \frac{1}{p^2 + m^2} \exp \left( -\frac{p^2 R^2}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\bar{p} \cdot \bar{b}}{2} \right)}{\left( \bar{p} \cdot \bar{b} \right)^2}
\end{align*}
\]

For \( m = 0 \) and \( \bar{b} \to 0 \), \( (3.0.7) \) simplifies

\[
\nabla \approx -C(D_\perp) g^2 \frac{M_\perp^2}{R_\perp^{D_\perp - 1}}
\]

with \( C \equiv (1/\sqrt{16\pi D_\perp}) (D_\perp/4\pi)^{D_\perp/2} \Gamma(D_\perp/2 - 1/2)/\Gamma(D_\perp/2 + 1/2) \). In this limit, the self-interactions between the string bits reduce to a Newtonian potential acting as a mean-field approximation. The Newtonian constant is identified as \( G_N \equiv g^2 D_\perp(D_\perp - 1)/2 \). Recall that the curvature effects of AdS\(_5\), which we are ignoring for simplicity, amounts to an effective \( D_\perp \to D_\perp(\lambda) \) in leading order on the transverse string propagator as we noted earlier. Thus,

\[
g^2 = 8\pi D_\perp^{-1-p} l_P^{D_\perp} = 8\pi D_\perp^{-1-p} g_s^2 l_s^{D_\perp} \equiv 2^{3-p-D_\perp} \pi D_\perp^{-1-p} g_s^2
\]

where in the last equality we reset \( 2l_s \equiv 1 \) as per our current conventions.

**IV. VARIATIONAL ANALYSIS**

For small perturbative interactions, we can modify the transverse Hamiltonian through

\[
H_\perp = 2M_\perp^2 + 2M_\perp \delta(2M_\perp) \equiv 2M_\perp^2 + 2M_\perp \nabla
\]
\( \mathcal{H}_\perp \) in Eq. 4.0.1 is difficult to analyze analytically in the presence of \( V \). We follow Thorn and Ogerman [32] and analyze it variationally by using a trial Gaussian distribution for each string bit

\[
\Psi(X^i_n) = \left(\frac{\omega_n}{\pi}\right)^\frac{d}{4} \exp \left[ -\frac{\omega_n}{2} (X^i_n)^2 \right] \quad (4.0.2)
\]

where the set of normal modes \( \omega_n \) will be defined below by minimizing the energy of the string in the presence of \( V \). In terms of (4.0.2) the scalar part is

\[
\mathcal{H}^0_\perp = \frac{D_\perp}{4} \sum_{n=1}^{N-1} \left( \omega_n + \frac{\Omega_n^2}{\omega_n} \right) + \frac{b^2}{\pi^2} \quad (4.0.3)
\]

and reduces to (2.0.10) when \( \omega_n = \Omega_n \) for \( V = 0 \). The effective mass of the string is

\[
M^2_\perp [\omega_n] = \frac{1}{2} \mathcal{H}^0_\perp = \frac{D_\perp}{8} \sum_{n=1}^{N-1} \left( \omega_n + \frac{\Omega_n^2}{\omega_n} \right) + \frac{b^2}{2\pi^2} \quad (4.0.4)
\]

The squared effective transverse radius is

\[
R^2_\perp [\omega_n] = \frac{1}{N} \sum_{k=0}^{N} \left( x^i_k - \frac{b_i}{N} \right)^2 = \frac{D_\perp}{4} \sum_{n=1}^{N-1} \frac{1}{\omega_n} \quad (4.0.5)
\]

With our conventions the total string energy is \( E[\omega_n] = 2M^2_\perp + 2M_\perp V \) depends on the set of variational parameters \( \omega_n \) which are fixed through the minimum

\[
\frac{\delta E}{\delta \omega_n} = \frac{\delta M^2_\perp}{\delta \omega_n} \left[ 2 - \frac{3\eta^2}{2} M_\perp \int \frac{d^{D_\perp+1}p}{(2\pi)^{D_\perp+1}} \frac{1}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b}{2} \right)}{(\theta b)^2} \right] \\
+ \frac{1}{D_\perp} \frac{\delta R^2_\perp}{\delta \omega_n} \frac{g^2 M^3_\perp}{\omega_n} \int \frac{d^{D_\perp+1}p}{(2\pi)^{D_\perp+1}} \frac{p^2}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b}{2} \right)}{(\theta b)^2} = 0 \quad (4.0.6)
\]

The mass and size variations can be made explicit

\[
\frac{\delta M^2_\perp}{\delta \omega_n} = \frac{D_\perp}{8} \left( 1 - \frac{\Omega_n^2}{\omega_n^2} \right) \quad \frac{\delta R^2_\perp}{\delta \omega_n} = -\frac{1}{4\omega_n^2} \quad (4.0.7)
\]

Inserting (4.0.7) into (4.0.6) and rearranging yield

\[
\omega_n^2 = \Omega_n^2 + \frac{\frac{\eta^2}{D_\perp} \int \frac{d^{D_\perp+1}p}{(2\pi)^{D_\perp+1}} \frac{p^2}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b}{2} \right)}{(\theta b)^2}}{1 - \frac{3\eta^2}{4} M_\perp \int \frac{d^{D_\perp+1}p}{(2\pi)^{D_\perp+1}} \frac{1}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b}{2} \right)}{(\theta b)^2}} \quad (4.0.8)
\]

where both \( M^2_\perp [\omega_n] \) and \( R^2_\perp [\omega_n] \) depend on the variational parameters through (4.0.4, 4.0.5). (4.0.8) define a highly non-linear set of equations for the variational parameters \( \omega_n \) defining the Gaussian ansatz (4.0.2). The generic solution is of the form \( \omega_n = \sqrt{\Omega_n^2 + \eta^2} \) with

\[
\eta^2 = \frac{\frac{\eta^2}{D_\perp} \int_0^{\infty} \int_0^{\pi} \int d\phi \ (\sin \phi)^{D_\perp-1} \frac{p^{D_\perp+2}}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b \cos \phi}{2} \right)}{(\theta b \cos \phi)^2}}{2^{D_\perp-1} \frac{D_\perp+2}{2} \Gamma \left( \frac{D_\perp}{2} \right) - \frac{\eta^2}{M_\perp} \int_0^{\infty} \int_0^{\pi} \int d\phi \ (\sin \phi)^{D_\perp-1} \frac{p^{D_\perp+2}}{p^2 + m^2} \exp \left( -p^2 \frac{R^2_\perp}{D_\perp} \right) \frac{4\sin^2 \left( \frac{\theta b \cos \phi}{2} \right)}{(\theta b \cos \phi)^2}} \quad (4.0.9)
\]
to be determined numerically. Note that for $b = 0$, (4.0.9) simplifies as

$$\eta^2 = \frac{M_\perp^2}{R_\perp^2} \frac{1}{2^{D_\perp+1} \pi D_\perp^2} \left( \frac{m^2 R_\perp^2}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \exp \left( -\frac{1+D_\perp}{2} \right) \Gamma \left( \frac{3+D_\perp}{2} \right) \left( \frac{m^2 R_\perp^2}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \Gamma \left( -\frac{1+D_\perp}{2} \right) \left( \frac{m^2 R_\perp^2}{D_\perp} \right)
$$

(4.0.10)

For $m = 0$, Eq. 4.0.10 further simplifies as

$$\eta^2 = \frac{M_\perp^2}{R_\perp^2} \frac{1}{2^{D_\perp+1} \pi D_\perp^2} \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \exp \left( -\frac{1+D_\perp}{2} \right) \Gamma \left( \frac{3+D_\perp}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \Gamma \left( -\frac{1+D_\perp}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)
$$

(4.0.11)

Note that for $b \neq 0$, (4.0.9) simplifies as

$$\eta^2 = \frac{M_\perp^2}{b^2} \frac{1}{2^{D_\perp+1} \pi D_\perp^2} \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \left( \frac{g^2 M_\perp}{D_\perp} \right) \Gamma \left( \frac{D_\perp+1}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \Gamma \left( -\frac{1+D_\perp}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)
$$

(4.0.12)

where

$$I[a] = \int_0^\infty dx \int_0^\pi d\phi \left( \frac{\sin \phi}{D_\perp} \right)^{D_\perp-3} \tan^2 \phi \left( \frac{x^2}{x^2 + m^2 b^2} \right) \exp \left( -\frac{x^2 R_\perp^2}{D_\perp b^2} \right) \sin^2 \left( \frac{x \cos \phi}{2} \right)
$$

(4.0.13)

The repulsion will cause the string bits to expand. A rerun of the precedent arguments yields now $\omega_n = \sqrt{\Omega_n^2 - \eta^2}$ with

$$\eta^2 = \frac{M_\perp^2}{b^2} \frac{1}{2^{D_\perp+1} \pi D_\perp^2} \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \left( \frac{g^2 M_\perp}{D_\perp} \right) \Gamma \left( \frac{D_\perp+1}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)^{\frac{D_\perp+1}{2}} \Gamma \left( -\frac{1+D_\perp}{2} \right) \left( \frac{g^2 M_\perp}{D_\perp} \right)
$$

(4.0.14)

The variational analysis will be now carried numerically for both the attractive and repulsive string interaction in the mean-field approximation.

V. NUMERICAL RESULTS

![Attractive interaction: $g = 0.3$ (Left). No interaction: $g = \tilde{g} = 0$ (Center). Repulsive interaction: $\tilde{g} = 0.3$ (Right).](image.png)

The Gaussian variation ansatz (4.0.2) can be used to define a variational probability distribution $|\Psi(X_n)|^2$ for the string amplitudes $X_n$ in the normal mode decomposition (2.0.4). Each string bit undergoes a Gaussian random walk.
which is free for $g = 0$ but constrained by the interaction through $\omega_n$ for $g \neq 0$. In Fig. 4 we show the spatial geometry of our discretized strings in $D_\perp = 3$ with a resolution $N = 200$ for the attractive interaction $g = 0.3$, no interaction and repulsive interaction $\tilde{g} = 0.3$. The string is stretched with $b = 5$. In Fig. 5 we show the transverse distribution of the string bits for an ensemble consisting of 40 stretched strings. The string bits are the dots and we have left out the string connection for a better visualization. The resolution is $N = 1/x = 200$. The attractive configurations are denser along $b$, while the repulsive configurations are spread out of $b$.

In Fig. 6 we show the growth of the transverse radius as measured by \((4.0.5)\) versus the resolution $N$ for different strengths of the attractive forces (left) and repulsive forces (right). For comparison, we also show the full length of the string

$$L \equiv \sum_{k=1}^{N} \sqrt{(x^k - x_{k-1})^2}$$ \hspace{1cm} (5.0.1)

The analogue change of the total length of the string with the resolution as defined in \((5.0.1)\) and the mass of the string as defined in \((4.0.4)\) are also shown in Fig. 7 and Fig. 8. While the length and mass scale linearly with $N$ whatever the interaction, the transverse size of the string bit distribution shows sensitivity to $N$. For $g = \tilde{g} = 0$ the transverse radius grows logarithmically as expected. As the attraction is switched on, the transverse radius asymptotes a constant about the string length. In contrast, as the repulsion is switched on, the transverse radius asymptotes a linear rise with the resolution as also noted in [32] in their non-relativistic string bit models with a variety of repulsive string interactions of different ranges. This supports our earlier earlier observation that at large resolution $N$ the mean-field approximation is generic.

We note that all attractive string self-interactions result in transverse area that are less than or equal to the Froissart bound. In contrast, all repulsive string self-interactions result in a transverse area that upsets the Froissart bound at asymptotic $N$ or asymptotically low-$x$. Thus our observation that saturation of the Bekenstein bound by the the string bits or wee gluons, follows from weakly attractive string-self interactions in conformity with the Froissart bound. We also note that our treatment of the interaction assumes weak self-interactions, or the smallness of the ratio

FIG. 5: Attractive interaction: $g = 0.3$ (Left). No interaction: $g = \tilde{g} = 0$ (Center). Repulsive interaction: $\tilde{g} = 0.1$ (Right).

FIG. 6: Attractive interaction: $g = 0.1, 0.2, 0.3$ (Left). Repulsive interaction: $\tilde{g} = 0.1, 0.2, 0.3$ (Right).
VI. SATURATION

At low-$x$ or large $N$ and $b = 0$, the transverse string density is high $\mathbf{n}_\perp(0,N) \approx N/R_{\perp}^{D_+}$ as $R_{\perp}$ shrinks under the effect of attractive self-interactions. For $0 < g < 0.3$ our numerical results yield $1.2 < R_{\perp} < 1.6$ in units where $2l_s = 1$, i.e. $2.4 < R_{\perp}/l_s < 3.2$. To understand the effects of the self-interaction on the string size configuration, we re-write...
schematically the squared mass \( E = 2M_\perp^2 + 2M_\perp V \) of the self-interacting string in terms of \( N \) and \( R_\perp \) dropping all numerical factors

\[
E \approx N^2 \frac{1}{R_\perp^2} + N^2 \frac{R_\perp^2}{\ln^2 N} - N^2 \frac{g^2 N}{R_\perp^{D_\perp - 1}} \tag{6.0.1}
\]

The first contribution in \((6.0.1)\) follows from the kinetic contribution in \((2.0.6)\) using the estimate \( N^2 p_i^2 \) and the uncertainty principle \( p_i \approx 1/R_\perp \). The second contribution in \((6.0.1)\) follows from the harmonic potential in \((6.0.1)\) using the estimate \( N^2(\Delta x_i)^2 \) with typically \( \Delta x_i \approx R_\perp/\ln N \) in the diffusive regime. The third contribution in \((6.0.1)\) is the potential contribution \( 2M_\perp V \) to the squared mass after using \( M_\perp \approx N \). Note that for \( g = 0 \) the minimum of \((6.0.1)\) yields the diffusive result \( R_\perp \approx \sqrt{\ln N} \) irrespective of the transverse dimension \( D_\perp \). For finite \( g \), the minimum of \((6.0.1)\) depends on the dimensionality \( D_\perp \). For our case \( D_\perp = 3 \) so the minimum of \((6.0.1)\) occurs for

\[
R_\perp \approx (1 - g^2 N)^{1/4} \sqrt{\ln N} \tag{6.0.2}
\]

For a relatively small attraction \( g^2 N \approx 1 \), \( R_\perp \) in \((6.0.2)\) undergoes a numerical change from an increasingly large and diffusive string to a small and fixed size string of about few string lengths. Fig. 10 (left) shows that for \( g = 0.1 \) the transverse size flattens out at about \( R_\perp \approx 1.85 \equiv 3.7l_s \approx 0.3 \) fm in the range \( 200 < N < 600 \). For fixed \( b \) the transverse area is ellipsoidal with a transverse bit density

\[
n_\perp(b, N) \approx \frac{N}{b(2R_\perp)^{D_\perp - 1}} \equiv \frac{N}{N_c} \frac{1}{g^2 l_s^{D_\perp}} \frac{b}{c} \frac{g^2 N_c}{(2R_\perp)^{D_\perp - 1}} \tag{6.0.3}
\]

The critical resolution \( x_c = 1/N_c \) at which this change takes place can be read from Fig. 10 (right)

\[
x_c = \frac{1}{N_c} \approx 0.1^2 \times 0.177 = 1.77 \times 10^{-3} \tag{6.0.4}
\]

for \( g = 0.1 \) with \( D_\perp = 3 \) and \( b = 5 \equiv 10l_s \approx 1 \) fm. We identify the onset \( x \approx x_c \) as the pre-saturation phase of the string at high resolution whereby its transverse area contracts to the string scale under weak self-attraction. However, the transverse string bit density is still dilute at this resolution since

\[
n_\perp(5, x) \approx \frac{x_c}{x} \frac{1}{5 l_s^3} \frac{1}{10 \times (4 \times 1.85)^2 \times 0.177} = \frac{x_c}{x} \frac{0.01}{l_s^3} \equiv \frac{x_c}{x} \frac{1}{l_s^3} \tag{6.0.5}
\]

or \( n_\perp(5, x_c) \approx 0.01/l_s^3 \). Recall that the Planck length \( l_p^3 = g^2 l_s^3 \) and that \( g^2 = (\pi/3)g_s^2 \) from \((3.0.9)\). At the saturation point or \( x = x_s \approx 0.01l_s \approx 10^{-5} \) the transverse density saturates the Bekenstein bound of one bit per transverse Planck area or \( n_\perp(5, x_s) \approx 1/l_p^3 \). We identify this point with the saturation scale or black hole regime. A schematic rendering of the pre-saturation and saturation phases in the low-x regime for \( b = 5 \) are shown in Fig. 11.

To summarize: the transverse string size distribution remains diffusive or logarithmic in \( N \) for small self-attractive interactions in the range \( 0 < g^2 N < 1 \). However for \( g^2 N \approx 1 - 1/\ln^2 N \) the transverse string size shrinks to a fixed
size comparable to the string length. Note that the change sets in at weak coupling with \( g^2 \approx 1/N \), for which the transverse density at \( b = 0 \) is

\[
\nu_\perp(0, x = 1/N) \approx \frac{N}{R_{\perp}^D} \Rightarrow \frac{1}{1/N} \frac{1}{l_p^D} \Rightarrow \frac{1}{l_p^D}
\]  

(6.0.6)

after restoring the string length. The first transition occurs in a very narrow range of \( g \) and thus appears to be first order by our analysis in (6.0.1, 6.0.2). It is a pre-saturation transition where the string size shrinks away from its diffusive growth and remains about fixed at a relatively dilute transverse string bit density. At much higher resolution or low-x a saturation transition takes place when the transverse string bit distribution reaches the Bekenstein bound of one string bit per Planck scale. This maybe intuitively understood by noting that low-x follows from large boosts a situation analogous to falling matter on a black-hole. For completeness, we note that self-repulsive strings increase in sizes following the substitution \( g^2 \to -g^2 \) in (6.0.6).

The present saturation observations are consistent with the saturation argument presented in [27–29] whereby the stringy but eikonalized dipole-dipole cross section was found to saturate in the impact parameter space when \( g^2 l_{s}^{D_{\perp}} n_{\perp} \equiv l_{p}^{D_{\perp}} n_{\perp} \approx 1 \) (see their Eq. 47). Although the relationship between the string coupling and the gauge coupling depends on the holographic extension of QCD used, for the generic model of AdS\(_5\) with a wall \( g_s = g_{YM}^2 / 4\pi \equiv \alpha_s \). So the stringy saturation to a black-hole occurs for weak coupling \( \alpha_s \approx \sqrt{x} \approx 1 \) at low-x with \( N = 1/x \). This geometrical picture yields an estimate of the saturation scale at low-x as \( l_s Q_s \approx l_s / l_p \approx 1 / x^{0.144} \) obtained empirically by Golec-Wustoff [47, 48], and \( l_s Q_s^{GW} \approx l_s / l_p \approx 1 / x^{0.114} \) obtained by Stoffers and one of us [27–29]. The discrepancy with the latter is due to dropping the curvature of AdS\(_5\) in the present analysis for simplicity.

The saturation of the Bekenstein bound is the string dual to the gluon saturation description in the color glass condensate model for fixed impact parameter using the Pomeron or string slope as a scale [49, 50]. The large string bit density (6.0.6) may upset the integrity of the string and perhaps a more appropriate description in terms of a fluid of string bits is needed. However, the physical presence of the string provides for a key property of the wee partons namely their transverse (Gribov) diffusion with a diffusion constant \( D_\perp = l_s^2 / 2 \) set by the string length. Also the exponential rise in the string density of states with its mass, provides for the most efficient way to scramble information and reach the Bekenstein bound and thus the saturation point. Finally, the self-interacting string in the mean-field approximation we have described may be viewed as perhaps a dual of a Pomeron branching into multiple Pomerons or fan-diagrams in Reggeon calculus [3].

The fluctuating string with fixed end-points exhibit azimuthal deformations in the transverse plane that can be characterized by the azimuthal moment [44, 51]

\[
\epsilon_n = \frac{1}{N} \sum_l N e^{i n \phi_l} \left( \frac{r_{\perp}}{r_\perp^n} \right)^n
\]  

(7.0.1)
where

\[ r_{\perp}^n = \frac{1}{N} \sum_{i}^{N} (r_{i}^\perp)^n \]  \hspace{0.5cm} (7.0.2)

with \( \phi \) the azimuthal angle as measured from the impact parameter line along \( \mathbf{b} \). \( r_{\perp} \) is the averaged size of the string on the transverse plane. For \( b = 0 \), we have \( \langle r_{\perp}^2 \rangle / 2 = R_{\perp}^2 / D_{\perp} \), where \( \langle \cdot \cdot \cdot \rangle \) is the average over string ensembles. Specifically, define \( x \equiv x_{\perp}^{1+1} \) and \( y \equiv x_{\perp}^{2+2} \) in the transverse plane, where \( x \) is parallel to the impact parameter \( \mathbf{b} \) and \( y \) perpendicular to it,

\[
x_{\perp}(k, \tau) = \sum_{n=1}^{N-1} X_n(\tau) \sin \left( \frac{nk}{N} \pi \right) + b_k \frac{k}{N}
\]

\[
y_{\perp}(k, \tau) = \sum_{n=1}^{N-1} Y_n(\tau) \sin \left( \frac{nk}{N} \pi \right)
\]  \hspace{0.5cm} (7.0.3)

Both \( X_n, Y_n \) are normally distributed with width \( 1/2\omega_n \) or

\[ X_n \sim \mathcal{N} \left( 0, \frac{1}{2\omega_n} \right) \quad \quad Y_n \sim \mathcal{N} \left( 0, \frac{1}{2\omega_n} \right) \]  \hspace{0.5cm} (7.0.4)

satisfy the normal distributions. We obtain

\[
x_{\perp}(k, \tau) \sim \mathcal{N} \left( b_k \frac{k}{N}, \Sigma_k^2 \right) \quad \quad y_{\perp}(k, \tau) \sim \mathcal{N} \left( 0, \Sigma_k^2 \right)
\]  \hspace{0.5cm} (7.0.5)

where

\[
\Sigma_k^2 = \sum_{n=1}^{N-1} \sin^2 \left( \frac{nk}{N} \pi \right) \frac{1}{2\omega_n}
\]  \hspace{0.5cm} (7.0.6)

For large \( N \), each of the transverse coordinates \( x_{\perp}(k, \tau) \) are almost independent. The azimuthal moments averaged over the independent transverse coordinates read

\[
\langle \epsilon_n \rangle = \frac{1}{\langle r_{\perp}^n \rangle} \left[ \frac{1}{N+1} \sum_{k=1}^{N-1} \int_{0}^{\infty} dr \int_{0}^{2\pi} d\phi \, r^{n+1} \cos(n\phi) \rho \left( r \cos \phi + \frac{b}{2}, r \sin \phi, k \right) + \frac{1 + (-1)^n}{N+1} \left( \frac{b}{2} \right)^n \right]
\]

\[ + \frac{i}{\langle r_{\perp}^n \rangle} \frac{1}{N+1} \sum_{k=1}^{N-1} \int_{0}^{2\pi} d\phi \, r^{n+1} \sin(n\phi) \rho \left( r \cos \phi + \frac{b}{2}, r \sin \phi, k \right) \]  \hspace{0.5cm} (7.0.7)

where

\[
\langle r_{\perp}^n \rangle = \frac{1}{N+1} \sum_{k=1}^{N-1} \int_{0}^{\infty} dr \int_{0}^{2\pi} d\phi \, r^{n+1} \rho \left( r \cos \phi + \frac{b}{2}, r \sin \phi, k \right) + \frac{2}{N+1} \left( \frac{b}{2} \right)^n
\]  \hspace{0.5cm} (7.0.8)

and

\[
\rho(x, y, k) = \frac{1}{2\pi \Sigma_k^2} \exp \left[ -\frac{(x - b_k \frac{k}{N})^2 + y^2}{2\Sigma_k^2} \right]
\]  \hspace{0.5cm} (7.0.9)

The Gaussian integrations can be done leading to

\[
\langle \epsilon_n \rangle = \frac{b^n}{\langle r_{\perp}^n \rangle} \left[ \frac{1}{N+1} \sum_{k=1}^{N-1} \left( \frac{1}{2} - \frac{k}{N} \right)^n + \frac{1 + (-1)^n}{N+1} \left( \frac{1}{2} \right)^n \right]
\]  \hspace{0.5cm} (7.0.10)
Note that the moments $\langle \epsilon_n \rangle$ are real and that all the odd moments vanish, i.e. $\langle \epsilon_n \rangle = 0$ for odd $n$. Simple algebra yields

$$
\frac{\langle r_T^2 \rangle}{b^2} = \frac{1}{N+1} \sum_{k=1}^{N-1} \left( \frac{1}{2} - \frac{k}{N} \right)^2 + \frac{2}{N+1} \sum_{k=1}^{N-1} \frac{\Sigma_k^2}{b^2} + \frac{2}{N+1} \left( \frac{1}{2} \right)^2
$$

(7.0.11)

and

$$
\frac{\langle r_T^4 \rangle}{b^4} = \frac{1}{N+1} \sum_{k=1}^{N-1} \left( \frac{1}{2} - \frac{k}{N} \right)^4 + \frac{8}{N+1} \sum_{k=1}^{N-1} \Sigma_k^2 \left( \frac{1}{2} - \frac{k}{N} \right)^2 + \frac{8}{N+1} \sum_{k=1}^{N-1} \Sigma_k^4 + \frac{2}{N+1} \left( \frac{1}{2} \right)^4
$$

(7.0.12)

In the limit $N \to \infty$, the moments simplify

$$
\Sigma_k^2 \approx \sum_{n=1}^{N} \frac{1}{4n} = \frac{R_T^2}{D_\perp}
$$

(7.0.13)

so that (for even $n$)

$$
\langle \epsilon_n \rangle \approx \frac{b^n}{\langle r_T^n \rangle} \int_0^1 d\tilde{k} \left( \frac{1}{2} - \tilde{k} \right)^n = \frac{b^n}{\langle r_T^n \rangle} \frac{1}{2^{n(1+n)}}
$$

(7.0.14)

$$
\frac{\langle r_T^2 \rangle}{b^2} \approx \frac{1}{12} + \frac{2}{D_\perp} \frac{R_T^2}{b^2}
$$

(7.0.15)

$$
\frac{\langle r_T^4 \rangle}{b^4} \approx \frac{1}{80} + \frac{2}{3} \frac{R_T^2}{b^2 D_\perp} + 8 \frac{R_T^4}{D_\perp^2 b^4}
$$

(7.0.16)

For small $b$, we obtain

$$
\langle \epsilon_2 \rangle \approx \frac{D_\perp}{24} \frac{b^2}{R_T^2}
$$

(7.0.17)

$$
\langle \epsilon_4 \rangle \approx \frac{D_\perp^2}{640} \frac{b^4}{R_T^4}
$$

(7.0.18)

For general $b$, the numerical results of $\langle \epsilon_2 \rangle$ and $\langle \epsilon_4 \rangle$ are displayed in Fig. 12 and Fig. 13 respectively.

![FIG. 12: Attractive interaction: $g = 0.1, 0.2, 0.3$ (Left). Repulsive interaction: $\tilde{g} = 0.1, 0.2, 0.3$ (Right).](image)
To show the transverse interaction it is also useful to use the cross moments \[44, 51\]

\[
\begin{align*}
(\epsilon_n \{2\})^2 &= \langle |\epsilon_n|^2 \rangle \\
(\epsilon_n \{4\})^4 &= -\langle |\epsilon_n|^4 \rangle + 2 \langle |\epsilon_n|^2 \rangle^2 \\
(\epsilon_n \{6\})^6 &= \frac{1}{4} \left[ \langle |\epsilon_n|^6 \rangle - 9 \langle |\epsilon_n|^4 \rangle \langle |\epsilon_n|^2 \rangle + 12 \langle |\epsilon_n|^2 \rangle^3 \right] \\
(\epsilon_n \{8\})^8 &= \frac{1}{33} \left[ -\langle |\epsilon_n|^8 \rangle + 16 \langle |\epsilon_n|^6 \rangle \langle |\epsilon_n|^2 \rangle + 18 \langle |\epsilon_n|^4 \rangle^2 - 144 \langle |\epsilon_n|^4 \rangle \langle |\epsilon_n|^2 \rangle^2 + 144 \langle |\epsilon_n|^2 \rangle^4 \right] \quad (7.0.19)
\end{align*}
\]

To characterize the initial azimuthal deformation of the string bits in the transverse collision plane, we show in Fig. 14 the pdf distributions of 1000 randomly generated strings at a resolution of \(N = 200\) with no self-interactions \(g/g = 0\). The pdf shown are for the distributions in \(\varepsilon_{2,3,4}\) respectively. We also show in Fig. 15 the pdf distributions of 1000 randomly generated strings at a resolution of \(N = 200\) undergoing string bit attractions with \(g = 0.3\) in the mean-field approximation. Note the strong dipole deformation in the leftmost figure. The same pdf for the repulsive case with \(\tilde{g} = 0.3\) are shown in Fig. 16. The linear spreading of the string bits with the resolution \(N\) causes the azimuthal deformations to be relatively uniform.

For completeness we show the behavior of the cross moments with the resolution for attractive, non-interacting and repulsive strings in Fig. 17, Fig. 18 and Fig. 19 respectively by sampling 1000 times a single string streched with \(b = 5\). The attraction is set at \(g = 0.3\) while the repulsion at \(\tilde{g} = 0.3\) for the infinite range case with \(m = 0\). Recall that the realistic case of a massive glueball or scalar mass \(m\) is amenable to \(m = 0\) by appropriately decreasing \(g\) or \(\tilde{g}\). In a typical pp collision at collider energies, we expect to exchange about 10 such long strings \[27, 29\]. In Fig. 20, Fig. 21 and Fig. 22 we show the same cross moments following from the exchange of 5 typical strings streched at \(b = 5\) sampled 200 times for the attractive, non-interacting and repulsive case respectively. The case where 10 string are exchanged is shown in Fig. 23, Fig. 24 and Fig. 25 for the same arrangements of parameters with each 10 string event sampled 100 times. The critical moments for the pre-saturation coupling \(g \approx 1/\sqrt{N} \approx 0.01\) are not much different from the \(g = 0\) presented here. We note that \(\epsilon_n \{4\} \approx \epsilon_n \{6\} \approx \epsilon_n \{8\}\) in agreement with suggestion made in \[51\]. The more string exchanges, the denser and more symmetric the transverse string bit distribution for a fixed resolution \(N\), the smaller the cross moments. Fig. 24 should represent typical cross moments in pp collisions at collider energies.
such as RHIC and LHC for minimum bias events. For the high multiplicity pp and pA events reported at LHC hot string configurations near the Hagedorn temperature are needed. They will be discussed in a sequel.

VIII. CONCLUSIONS

Long holographic strings in walled AdS$_5$ and $D_{\perp} = 3$ provides for a dual description of diffractive scattering and production as well as low-$x$ DIS \cite{27}. Although a key aspect of AdS$_5$ is its conformality which translates to the conformal character of QCD in the UV, the essentials of the walled AdS$_5$ construction for the holographic string with a large rapidity interval can be captured by a relatively cold transverse string with an effective transverse dimension

$\phi$
2 < D_⊥ < 3. The Pomeron intercept follows from the zero point motion or Luscher term of the free transverse string with D_⊥/12, and the Pomeron slope is fixed by the string tension.

We have suggested that at low-x, DIS scattering of a small dipole of size 1/Q scattering off a fixed target dipole can be regarded as the exchange of a stretched string with fixed parameter b with a large rapidity interval ln(1/x). Although the DIS structure function averages over all impact parameters, the dominant contribution to this averaging stems from relatively large b/l_s ≈ √ln(1/x) in units of the string scale l_s ≈ 0.1 fm. Therefore low-x studies could be turned to the studies of a transverse holographic string at higher and higher resolution, a dual description to the wee parton description in perturbative QCD. An essential aspect of the partonic description is Gribov transverse diffusion which arises naturally in the quantum string description as emphasized by Susskind and others [33, 34].

The wee parton description at low-x can be mapped on a discretized transverse string in N = 1/x string bits [35, 36]. We have shown that the quantum description of a free transverse and discretized string in D_⊥ = 3 results in highly deformed geometries for the string sizes and shapes when the string is stretched at fixed impact parameter. We have suggested that at high resolution or string bits, string self-interactions can be captured by a mean-field pair interaction between the string bits. The pair interaction is characterized by a coupling g and a range 1/m both of which are inter-changeable by re-scaling. The holographic origin of the transverse string allows for the identification of g with the Newtonian constant of the bulk gravity for m = 0. As a result a Planck scale emerges for holographic strings at high resolution in D_⊥ = 3. In terms of the gauge coupling α_s, the holographic Planck scale is identified as l_P ≈ α_s^{2/3}l_s.

For relatively weak self-interactions we have found that the string initial diffusive growth undergoes a first order
change into a smaller and fixed size transverse string of the order of few string lengths at a resolution of \( x_c \approx 0.001 \) and for a small string coupling that translates to a gauge coupling of \( \alpha_s \approx g_s \approx 0.1 \). We have identified this change with a pre-saturation stage whereby the string geometry is fixed and small, but the transverse string bit density is still dilute on the Planck scale \( l_3^\perp \approx 0.01 \). At a much higher resolution or \( x_s/x_c \approx 0.01 \) we have found that the transverse string bit density saturates the Bekenstein bound of one bit per Planck scale. We have identified this point with the saturation scale.

The geometry of the string bit distributions emerging from stretched strings for a typical impact parameter of \( b = 5 \equiv 10 l_s \) is rich in structure and transverse deformation. We have presented a detailed study of its transverse moments and moment distributions for single and multiple string exchanges. These prompt and deformed distributions can be used to initialize the prompt parton distributions in current \( pp \) and \( pA \) collisions in colliders at high resolution or low-x. The large reformations observed in this analysis show that they can yield large transverse asymmetries in prompt multi-particle production in the Pomeron kinematics. Also they may translate to large transverse momentum asymmetries in the flow analyses of multiplicity at current collider energies. We plan to address some of these issues next.

IX. ACKNOWLEDGEMENTS

We thank Dima Kharzeev and Edward Shuryak for discussions. This work was supported by the U.S. Department of Energy under Contract No. DE-FG-88ER40388.
