ABSTRACT
We present a first principle approach to obtain analytical predictions for spherically-averaged cosmic densities in the mildly non-linear regime that go well beyond what is usually achieved by standard perturbation theory. A large deviation principle allows us to compute the leading-order cumulants of average densities in concentric cells. In this symmetry, the spherical collapse model leads to cumulant generating functions that are robust for finite variances and free of critical points when logarithmic density transformations are implemented. They yield in turn accurate density probability distribution functions (PDFs) from a straightforward saddle-point approximation valid for all density values. Based on this easy-to-implement modification, explicit analytic formulas for the evaluation of the one- and two-cell PDF are provided. The theoretical predictions obtained for the PDFs are accurate to a few percent compared to the numerical integration, regardless of the density under consideration and in excellent agreement with N-body simulations for a wide range of densities. This formalism should prove valuable for accurately probing the quasi-linear scales of low redshift surveys for arbitrary primordial power spectra.

Key words: cosmology: theory — large-scale structure of Universe — methods: analytical, numerical

1 INTRODUCTION

Given the increasing amount of data released by large galaxy surveys, such as the BOSS survey (Dawson et al. 2013), DES (Abbott et al. 2005) and in the coming years Euclid (Laureijs et al. 2011) and LSST (LSST Science Collaboration et al. 2009), it is becoming crucial for astronomers to exploit observations of the large-scale structure of the Universe in the best possible way. This task is difficult as the large-scale structure of the Universe is the result of the interplay between the cosmological parameters, such as the amount of dark matter and dark energy, the initial metric perturbations, the non-linearities in the cosmic fluid evolution, not to mention the impact of baryonic physics on small-scales – down to the stellar mass scale – through the back-reaction of baryons onto the large-scale structures. Making use of the statistical properties of the large-scale structure to extract information on fundamental cosmological parameters is therefore a daunting task.

Hence it is crucial to tailor complementary sets of observables that can help disentangle all of those effects. The most commonly used tools to extract statistical information from the observed galaxy distribution are the N-point correlation functions (e.g. Scoccimarro et al. 1998), which quantify how galaxies are clustered, and primarily the two-point correlation function or its Fourier counterpart, the power spectrum. Observations of the cosmic microwave background strongly support the idea that the initial metric perturbations followed Gaussian statistics to an extremely good accuracy (Planck Collaboration et al. 2015). As a result, the statistical properties of the large-scale structure of the universe at its early stages, or equivalently in this context at large enough scales, are entirely characterized by this two-point correlation function.

At later times, when the typical density contrasts (or velocity gradients) become large, the cosmic fluid rapidly develops nonlinear structures. In particular the power spectrum of the density field evolves nontrivially via the in-
duced mode coupling. This can be captured for instance with the help of perturbation theory (PT) approaches (see Bernardeau et al. 2002; Crocce & Scoccimarro 2006; Taruya & Hiramatsu 2008; Pietroni 2008; Taruya et al. 2012; Carrasco, Hertzberg & Senatore 2012). Yet, the strength of these couplings, and in particular the coupling between small and large scales (see Bernardeau, Taruya & Nishimichi 2014; Blas, Garny & Konstandin 2013; Nishimichi, Bernardeau & Taruya 2014), limits in part the relevance of such techniques. One should indeed keep in mind that for PT, the density perturbations are assumed to be small everywhere, which is obviously not the case in the present universe. Overcoming such a limitation is very challenging and usually relies on phenomenological methods qualified on $N$-body simulations, such as the halo models (Cooray & Sheth 2002).

There exists however a first principle approach based on the application of Large Deviation Theory which deals with the rate at which probabilities of certain events decay as a natural parameter of the problem decreases rapidly enough to zero. The applicability of Large Deviation Theory in this context has been discovered and partially explored in various cosmological papers over the last decades (e.g. Bernardeau 1992, 1994; Bernardeau & Valageas 2000) and more precisely in Bernardeau, Pichon & Codis (2014), although not from the Large Deviation Principle (LDP) perspective that was recently presented in Bernardeau & Reimberg (2015) in this context. The identification of a regime where LDP can be applied gives a sound framework to explore statistical properties of the fields without assuming that field fluctuations are small everywhere, the only assumption being that the typical values – the variance – of the quantities under consideration, for instance of the density filtered at a given scale, are small. The reach of such an approach is then potentially far wider than standard PT. The drawback is that demonstrating the applicability of the LDP is in general very complicated, and the proof is only possible in specific geometries that are special enough to allow an explicit mapping between the final configuration and the initial field values. Once established, the LDP implies that the probability distribution has an exponential decay that is driven by the so-called rate function. In the LSS context, the rate function can be found for highly symmetric configuration (spherical or cylindrical symmetry) for which the full non-linear evolution of the dynamical equations (the so-called spherical or cylindrical collapse model) are known exactly. Indeed matter contained in a spherical cell (in a static, asymptotically flat spacetime) evolves independently of the external ambient, hence analytic solutions of the gravitational collapse can be obtained explicitly. For corresponding observables, such as densities in concentric spheres or discs, they yield very accurate analytical predictions in the mildly non-linear regime, well beyond what is usually achieved using other estimators.

The aim of the paper is to extend further the use of such an approach. In particular it will be stressed that in the LDP context, any nonlinear functions of the density in concentric cells can be considered, via the so called contraction principle as explained in Bernardeau & Reimberg (2015), hence broadening the range of possible applications. We will see how such choices affect the predicted probability density functions (PDFs), and more importantly how it opens the way to having fully analytical predictions that can straightforwardly be implemented in real surveys while considering arbitrary underlying cosmic models.

A particular emphasis will be put on logarithmic transformations of the density field, which have attracted some interest in the context of cosmic structure formation since the PDF of the density field was found to be nearly log-normal (Hubble 1934; Hamilton 1985; Coles & Jones 1991; Colombi 1994; Kayo, Taruya & Suto 2001). In particular, the power spectrum of the log-density is known to be less prone to non-linearities (Neyrinck, Szapudi & Szalay 2009; Greiner & Enßlin 2015) which stimulated analytical studies within perturbation theory. In Szapudi & Kaiser (2003) tree-level perturbation theory in the log-density field was considered and connected to the dominant part of first-order PT in the density and higher partial loop corrections. Based on a general mapping for nonlinear bias formulated by Fry & Gaztanaga (1993), especially the variance of the log-density was found to be smaller than the variance of the density. Note however, that Wang et al. (2011) showed that the log-density does not significantly enhance the validity regime of standard PT calculations based on the density. Carron (2011) also highlighted the limited information of log-normal statistics in the strongly non-linear regime. In this paper, we are revisiting the use of log-densities in a different and complementary context: large deviation statistics.

The idea here is not to rely on the Gaussianity of the log-density field but on the weak dependence of its cumulants with respect to the variance of the density field. Let us make clear that here we do not expect the log-density to arise naturally a priori, but rather as a prime example of a nonlinear mapping that will prove particularly advantageous. The adequacy of this approach will be established by means of $N$-body simulations verifying the weak dependence of the cumulants of the log-density on the variance. This key property will indeed allow us to extend the domain of applicability of the LDP well beyond its zero variance limit. We will in particular build very accurate analytical models based on the saddle approximation for the one and two cells PDF of the density within concentric cells which match simulations up to variances of order one.

The outline of the paper is the following. We present in Section 2 the large deviation principle that allows to obtain one-point statistics for the density in concentric spheres. We describe how to obtain the density PDF from the rate function using spherical collapse dynamics and the saddle-point approximation, and demonstrate how the log-density mapping remedies technical difficulties that impeded this construction for the density. In Section 3 we present $N$-body measurements of the cumulants and their generating functions for both the density and the log-density in order to establish that the log-density is more resilient to changes in the variance. We formulate a mapping to relate the cumulants of the log-density to those of the density and discuss their relation based on measurements as well as analytical predictions relying on the LDP and perturbation theory, respectively. In Section 4 we finally present the analytic predictions from the LDP applied to the log-density for the one and two-cell PDF of the density, which give an excellent match to the simulations and substantially extend the reach of the saddle-point approximation. Section 5 wraps up discusses promising perspectives.
2 THE LOG DENSITY MAPPING

For the sake of clarity, let us first present the formalism and explain how a change of variable can allow for fully analytical predictions. Consider one sphere $S$ of radius $R$ centred on a given location in space. Our goal is to derive a working model for the PDF, $\mathcal{P}_R(\hat{\rho})$, of the density in $S$ denoted by $\hat{\rho}$ and rescaled so that $⟨\hat{\rho}\rangle = 1$. In order to achieve this, we will rely on the LDP to connect the cumulant generating function to the PDF, while assuming that the variance, $\sigma^2(R)$, of the field fluctuation within that sphere is small enough. For a complementary intuitive rather than a mathematically precise description of the connection, see Appendix A and Bernardeau, Codis & Pichon (2015).

2.1 The Large Deviation Principle

Let us consider the scaled cumulant generating function (SCGF), $\varphi_\mu(\lambda)$, defined from the cumulant generating function, $\varphi(\lambda)$, as

$$\varphi_\mu(\lambda) = \lim_{\sigma^2 \to 0} \sigma^2 \varphi \left( \frac{\lambda}{\sigma^2} \right) = \lim_{\sigma^2 \to 0} \sigma^2 \log \left[ e^{\frac{\lambda^2}{\sigma^2}} \right],$$

where $⟨\cdot⟩$ stands for ensemble average, and $\sigma^2$ is, or scales like, the variance of $\hat{\rho}$. The existence of a LDP for the variable $\hat{\rho}$ implies that the SCGF is given by the Legendre-Fenchel transform of the rate function, $\psi(\hat{\rho})$, as

$$\varphi_\mu(\lambda) = \sup_{\hat{\rho}} \{ \lambda \hat{\rho} - \psi(\hat{\rho}) \},$$

where the rate function is by definition the leading behaviour of the log of the density PDF,

$$\psi(\hat{\rho}) = -\lim_{\sigma^2 \to 0} \sigma^2 \log \mathcal{P}_R(\hat{\rho}).$$

A key consequence of the LDP of relevance here is that different rate functions of functions (or functionals) of random variables related by continuous maps are closely connected through the contraction principle. More precisely, we have

$$\psi(\hat{\rho}) = \inf_{\{\tau\} \in \mathcal{F}} \psi_\tau(\{\tau\}),$$

whatever the continuous transform $\mathcal{F}$ one considers (it does not have to be monotonic nor single valued). The infimum in equation (4) encodes the general idea that any large deviation follows the least unlikely of all the unlikely transformations. This transformation can be an active mapping (e.g. temporal evolution) or a passive one (e.g. taking the log of the density); we will make use of both here.

Consequences of this principle are numerous: in particular, the rate function of $\hat{\rho}$ can be computed from the initial density field if the mapping between the initial configuration and the final field value is known, or more specifically, if one is able to identify the leading field configuration that will contribute to this infimum.

In spherically symmetric configurations, this is precisely what can be conjectured: $\hat{\rho}$ is in one-to-one correspondence with the linear density contrast in a cell centered on the same point and that contains the same mass. Then, one can give the explicit expression of the rate function

$$\psi(\hat{\rho}) = \sigma^2(R) \Psi_R(\hat{\rho}), \quad \Psi_R(\hat{\rho}) = \frac{1}{2\sigma^2(R)} \tau(\hat{\rho})^2,$$

where the smoothing scale $r$ is such that $r^3 = R^3 \hat{\rho}$ and $\hat{\rho} = \zeta_{SC}(\tau)$, with $\zeta_{SC}$ the non-linear mapping between the linear overdensity within radius $r$ and the non-linear density within radius $R$ as given by the spherical collapse dynamics (see Bernardeau & Reimberg (2015) for details). The decay-rate function $\Psi_R(\hat{\rho})$ drives the exponential decay of the PDF, as one can see from equation (3).

Moreover, and this is the property which is central to this paper, the same principle states that equation (5) is also the rate function of any variable $\mu$, corresponding to a (monotonic) transformation of $\hat{\rho}$, $\mu = \mu(\hat{\rho})$, so that $\Psi_R(\mu) = \Psi_R(\hat{\rho}(\mu))$. Consequently, the scaled cumulant generating function, $\varphi_{R,\mu}(\lambda)$, of such a variable is nothing but the Legendre-Fenchel transform of the corresponding rate function, defined as

$$\varphi_{R,\mu}(\lambda) = \sup_{\tau} \left\{ \lambda \mu(\tau) - \frac{\sigma^2(R)}{2\sigma^2(\tau)} \tau^2 \right\}.$$  

At this stage it is important to note that the Legendre-Fenchel transform reduces to a Legendre transform provided the rate function is convex. In that case, the Legendre transform can be computed from simple variational calculations such that $\mu(\lambda)$ is given implicitly by the stationary condition $\lambda = \partial \psi / \partial \mu$. Note also that, whereas the rate function values are the same for corresponding variables, its convexity properties depends on the choice of variables.

What are the subsequent steps to build the density PDF? It can be obtained from an Ansatz for the cumulant generating function which is assumed to naturally match its asymptotic $\sigma^2 \to 0$ limit,

$$\phi_{R,\mu}(\lambda) = \frac{1}{\sigma^2} \varphi_{R,\mu}(\lambda \sigma^2),$$

so that we are now extrapolating the LDP result to finite variances. The last step is to compute the inverse Laplace transform of the moment generating function, so as to write the PDF of $\hat{\rho}$ for a given variance $\sigma^2(\tau)$ as

$$\mathcal{P}_R(\hat{\rho}) = \int_{-\infty}^{+\infty} \frac{d\lambda}{2\pi i} \exp[-\lambda \hat{\rho} + \phi_{R,\mu}(\lambda)],$$

where $\phi_{R}(\lambda)$ is a function of $\sigma^2(\tau)$ given by equation (7). Here $\sigma^2$ can actually be adjusted to match the measured variance if necessary. The integration in equation (8) requires an analytic extension of the cumulant generating function in the complex plane, which has also been noted in Fry (1985); Gaztañaga, Fosalba & Elizalde (2000); Valageas (2002) to name just a few examples of previous work.

The analytical properties of this extension depend on the choice of variables. In previous works including Bernardeau, Pichon & Codis (2014) the freedom in choosing a mapping $\mu = \mu(\hat{\rho})$ was ignored and only $\hat{\rho}$ was considered to obtain the PDF.¹ This leads to a critical point along the real axis that a better choice of variable can avoid, as we precisely show now.

2.2 Avoiding criticality by using the log-density

It should be clear from equation (8) that our ability to make predictions on the shape of the PDF depends crucially on the

¹ However, the LDP was used implicitly via the active mapping between initial and final density, see Appendix A.
analytic properties of the cumulant generating functions. In particular, the existence of critical points for \( \phi_R(\lambda) \) that arise from the Legendre transformation of the decay-rate function \( \Psi_R(\rho) \) can make it difficult to perform the explicit integration in the complex plane. In the low-density regime, the inverse Laplace transform in equation (8) can in principle be computed via a saddle-point approximation, taking advantage of the fact that the variance is small, leading to the form

\[
P_R(\rho) = \sqrt{\frac{\Psi''_R(\rho)}{2\pi}} \exp\left(-\Psi_R(\rho)\right). \tag{9}
\]

Note that, the saddle point approximation has been used in Fry (1985) in combination with a cumulant generating function from a hierarchical model rather than spherical collapse dynamics. Based on this, an Edgeworth expansion\(^2\) was performed by expanding the normalized saddle point PDF around a Gaussian in Gaztañaga, Fosalba & Elizalde (2000). More recently, the leading order of the cumulant generating function has been obtained from a diagrammatic approach to the hydrodynamic equations in Bernardeau (1992) that was shown to lead to spherical collapse dynamics. Subsequently, in Valageas (2002), spherical collapse has been shown to give the leading contribution to the cumulant generating function by means of a steepest descent method (sometimes also referred to as saddle point approximation) providing a non-perturbative argument that goes beyond the diagrammatic approach initially employed. In the following, we will adopt the approach to rely on spherical collapse dynamics to obtain the decay-rate function.

When the saddle point approximation is applicable, that is when the decay-rate function is convex (\( \Psi''_R(\rho) > 0 \)), it provides a very good approximation to the exact numerical integration (Bernardeau, Pichon & Codis 2014). However, as mentioned before, it has been shown in Bernardeau (1994) that typically there is a critical value for \( \rho_c \) at finite distance where \( \Psi''_R(\rho_c) = 0 \) above which the Legendre transform of \( \Psi_R \) is not defined, which prevents the practical use of equation (9). Although there exist alternative forms to the PDF based on the behaviour of the cumulant generating function near its critical point, they are only accurate in the very high density regime and do not encompass the intermediate region around \( \rho \approx \rho_c \). The central point we make in this paper is that this difficulty can be alleviated with an adequate change of variable \( \hat{\rho} \to \rho \) such as the log of the density, \( \mu = \log \hat{\rho} \). The construction of the density PDF is then obtained with the following steps:

\[
P_{R,\mu}(\mu) \text{d}\mu = \int_{-\infty}^{+\infty} \frac{d\lambda}{2\pi i} \exp[-\lambda \mu + \phi_{R,\mu}(\lambda)], \tag{10a}
\]

\[
P_R(\hat{\rho}) \text{d}\hat{\rho} = P_{R,\mu}(\log(\hat{\rho})) \frac{d\hat{\rho}}{\hat{\rho}}, \tag{10b}
\]

with the further simplification brought by the saddle-point expression of the density PDF in equation (10), which eventually leads to

\[
P_R(\rho) = \sqrt{\frac{\Psi''_R(\rho)}{2\pi}} \exp\left(-\Psi_R(\rho)\right). \tag{11}
\]

It has to be noted that the two formulæ, equations (9) and (11), are based on two distinct assumptions when extrapolated to finite values of \( \sigma \). Namely either \( \phi_{R,\mu}(\lambda) = \varphi_{R,\mu}(\lambda^2)/\sigma^2 \) or \( \phi_{R,\mu}(\lambda) = \varphi_{R,\mu}(\lambda^2)/\sigma^2 \). We will see more precisely in the following that although the contraction principle ensures that the scaled cumulant generating functions are both independent of such assumptions – their limit is left unchanged for \( \sigma \to 0 \) – this is not the case when the variance is finite. This is why one variable turns out to be a better choice than the other in practice.

Let us first examine the critical behaviour of \( \Psi_R(\hat{\rho}) \) and \( \Psi_R(\rho) \), respectively. The starting point is the quadratic form (5) for \( \Psi_R(\tau) \) converted to a function of the final density \( \hat{\rho} \) by inverting the spherical collapse relation to obtain \( \tau(\hat{\rho}) \). For an EdS universe, the spherical collapse dynamics can be approximated as

\[
\hat{\rho}(\tau) \simeq \frac{1}{(1 - \tau/\nu)^{\nu}}, \quad \nu = \frac{21}{13}, \tag{12}
\]

which is known to reproduce well the spherical collapse in an EdS Universe (described for example in Fosalba & Gaztañaga 1998) for the range of densities of interest as has been shown in (Bernardeau 1992). For simplicity, we now assume for the variance a power law initial power spectrum with index \( n_s \approx -1.5 \)

\[
\sigma^2(R) = \sigma^2(R_p) (R/R_p)^{-(n_s+3)}, \tag{13}
\]

where \( R_p \) is a pivot scale. In Section 4 this simplifying assumption is amended to account for a running of the spectral

\[\text{Figure 1. Effect of a logarithmic density-transformation } \hat{\rho}(\mu) \text{ on the domain of definition of } \sqrt{\Psi''_R} \text{ set by the positivity condition } \Psi''_R > 0. \text{ Results for the density } \mu = \hat{\rho} \text{ (thin lines)} \text{ and the log-density } \mu = \log \hat{\rho} \text{ (thick lines)} \text{ are displayed for different initial spectral indices } n_s = -1.25, -1.5, \cdots, -3.25 \text{ (colored as indicated in the legend). This comparison shows that the log-transform is able to avoid the criticality of the decay-rate function } \Psi_R \text{ for all densities over a wide range of indices typically } n_s > -2.4. \text{ On the contrary, a critical point is met for all indices when the variable is the density field itself.} \]
index. In that case, the variance is approximated by
\[ \sigma^2(R) = \frac{2\sigma^2(R_p)}{(R/R_p)^{n_1+3} + (R/R_p)^{n_2+3}}, \]
(14)
where \( n_1 \) and \( n_2 \) are chosen to reproduce the linear theory index \( n(R) = \frac{3 - d\log(\sigma(R))/d\log R}{d\log(\sigma(R))/d\log R} \) and running, \( \alpha(R) = d\log(n(R))/d\log R \) at the pivot scale \( R_p \). For a generalization to arbitrary initial power spectra see Section 5.2.

The functions \( \Psi_k[R, \rho] \) and \( \Psi_k[R, \mu/\rho] = \Psi_k[R, \hat{\rho}] + \Psi_k[R, \rho/\hat{\rho}] \) entering the square root in respectively equation (9) and equation (11) are shown in Fig. 1 for various values of the power law index \( n_\sigma \). It can easily be checked that for most spectral indices of interest we always have \( \Psi_k[R, \mu] > 0 \). Conversely, we recover the existence of a critical value \( \hat{\rho}_c \approx 2.36 \) pointed out in Bernardeau, Pichon & Codis (2014) for \( \Psi[R, \hat{\rho}] \). One can see that the mapping \( \rho = \exp \mu \) avoids the criticality for all relevant densities and power spectrum indices \( n_\sigma \geq -2.4 \).

### 3 Cumulant Generating Functions

As stressed in the introduction, the application of the LDP gives access to the SCGF for the cumulants defined in equation (1) for the variable of interest. This quantity is at the heart of our constructions. It serves in particular as a model for the actual cumulant generating function – which is an observable on itself – as in equation (7). Such a function can be measured, or can be used to build the density PDFs as shown in the previous Section.

#### 3.1 Scaled cumulant generating functions

Let us re-express the SCGF in terms of the field cumulants,
\[ \varphi_x(\lambda) = \lim_{\langle \tilde{x}^{2} \rangle \to 0} \sum_{p=1}^{\infty} \frac{\langle \tilde{x}^{p} \rangle_{c}}{\langle \tilde{x}^{2} \rangle_{c}^{p-1}} \frac{\lambda^{p}}{p!}, \]
(15)
for a given variable \( \tilde{x} \). It involves naturally the reduced cumulants \( S_{\rho}[\tilde{x}] \) defined as
\[ S_{\rho}[\tilde{x}] = \frac{\langle \tilde{x}^{p} \rangle_{c}}{\langle \tilde{x}^{2} \rangle_{c}^{p-1}} \quad \forall p \geq 2, \]
(16)
but evaluated in their low-variance limit. Equation (7) contains however non-trivial physical assumptions. From a PT point of view, and for Gaussian initial conditions as assumed here, the leading low-variance limit of \( S_{\rho}[\tilde{x}] \) are their so-called tree order expression\(^4\),
\[ \lim_{\langle \tilde{x}^{2} \rangle \to 0} S_{\rho}[\tilde{x}] = S_{\rho}^{\text{tree}}[\tilde{x}], \]
(17)
The strength of the LDP applied in this context is to provide means to compute all the tree order expression of the reduced cumulant at once, for any variable such as \( \hat{\rho} \) or \( \mu \). Then the form (7) relies on the hypothesis that either \( S_{\rho}[\hat{\rho}] \) or \( S_{\rho}[\mu] \) are independent of variance, depending on the chosen variable. Finally, notice that, in the specific case of the variable\(^5\) \( \mu = \log \rho \), there exists a simple way to compute the moments of \( \hat{\rho} \) from the cumulant generating function of \( \mu \) as
\[ \langle \hat{\rho}^{\prime} \rangle = \langle \hat{\rho}^{\prime} \rangle_{\rho} = \langle \rho^{\prime} \rho \rangle_{\mu} = \exp[\phi_{\mu}(\rho) - p \phi_{\mu}(1)] \).
(18)
It is then easy to predict the moments of the density from the SCGF. In particular, this allows to adjust the variance for \( \hat{\rho} \), once the variance for \( \mu \) has been chosen because
\[ \sigma_{\rho}^{2} = \frac{\langle \hat{\rho}^{2} \rangle}{\langle \hat{\rho}^{2} \rangle_{\rho}} - 1 = \exp \left[ \frac{\varphi_{\mu}(2\sigma_{\mu}^{2}) - 2\varphi_{\mu}(\sigma_{\mu}^{2})}{\sigma_{\mu}^{2}} \right] - 1. \]
(19)

#### 3.2 Cumulants as observables

From a theoretical point of view, the LDP does not give any indications about which physical assumption – whether \( S_{\rho}[\hat{\rho}] \) or \( S_{\rho}[\mu] \) should be kept constant – is better. PT calculations pushed to one-loop order could provide some indications, but no such results are known today. Hence, for now we must rely on results from numerical simulations. Those are described in Appendix B (see also Bernardeau, Pichon & Codis 2014). In Fig. 2, we show the numerical variations of the reduced cumulants \( S_{3}[\mu] \) and \( S_{4}[\mu] \) for both \( \hat{\rho} = \mu = \log \rho \) as a function of the variance for radii from \( R = 4 \) to \( 16 \) Mpc/h. We observe that the reduced cumulant for the log-density \( S_{\rho}[\mu] \) is smaller than that of the density \( S_{\rho}[\hat{\rho}] \), but also has a milder \( \sigma \)-dependence. This suggests that extrapolating the zero variance result for the log-density to finite variances is more adequate than doing so for the density and also that the cumulants of the log-density \( S_{\rho}[\mu] \) can be better captured by perturbation theory than those of the density \( S_{\rho}[\hat{\rho}] \), as will be demonstrated in the following.

Irrespective of the choice we make, it is always possible to express the reduced cumulants of one variable in terms of the other. The procedure is detailed in Appendix C. It relies solely on the mapping between the log-density \( \mu \) and the normalized density \( \hat{\rho} = \exp \mu / \langle \exp \mu \rangle \). We report here on some results showing the expression of the variance and first two nontrivial reduced cumulants
\[ \sigma_{\rho}^{2} = \langle \hat{\rho}^{2} \rangle - \frac{3}{2} \langle S_{\mu}[\mu] \rangle + \frac{7}{2} \langle S_{\mu}[\mu] \rangle - 2 \langle S_{\mu}[\mu] \rangle^{2} + 1 \right) + O(\sigma_{\mu}^{4}), \]
(20)
\[ S_{3}[\rho] = S_{3}[\mu] + 3 \]
(21)
\[ + \sigma_{\mu}^{2} \left[ \frac{3}{2} S_{4}[\mu] + 2 S_{3}[\mu] - 2 S_{4}[\mu] \right] + O(\sigma_{\mu}^{4}), \]
\[ S_{4}[\rho] = 16 + 12 S_{3}[\mu] + S_{4}[\mu] + O(\sigma_{\mu}^{4}). \]
(22)
In particular, equation (21) can be used to determine the third cumulant of the density \( S_{3}[\rho] \) from the measured cumulants of the log-density \( S_{3/4}[\mu] \). This is illustrated in Fig. 2 (top panel); it shows how well \( S_{3}[\rho] \) measured from the simulation can be recovered from the measured \( S_{3/4}[\mu] \) and that the seemingly larger error bars on \( S_{3/4}[\rho] \) for large radii indeed lead to comparable or even smaller error bars on \( S_{3}[\rho] \).

Furthermore, assuming that the cumulants of the log-density \( S_{\rho}[\mu] \) are equal to their tree order expression, allows

---

3 For smaller indices \( n_\sigma < -2.4 \) it is possible to iterate the logarithmic mapping to prevent \( \Psi_R \) from becoming critical.

4 This comes from their diagrammatic representations that all reduces to trees, see Bernardeau et al. (2002) for details.

5 Note that, \( \mu = \log \rho \) is used as shorthand notation for \( \hat{\rho} = \exp \mu / \langle \exp \mu \rangle \) with \( \langle \mu \rangle = 0 \).
3.3 Cumulant generating functions as observables

Cumulant generating functions themselves are measurable in N-body simulations. In Fig. 4 we show the scaled cumulant generating function $\varphi_R(\lambda) = \sigma^2 \Phi_R(\lambda / \sigma^2)$ for the log-density $\mu$ and the density $\rho$ as measured from the N-body simulation for different radii and redshifts. For the SCGF of the density displayed in the upper panels the emergence of a critical point can be observed which makes the error bars large. Note that the dependence of the variance $\sigma^2$ on radius $R$ and redshift $z$ is such that decreasing $R$ and decreasing $z$ both increase the variance. Therefore a SCGF with a narrow band for different radii $R$ and redshifts $z$ signals robustness against increasing the variance from its zero limit upwards. As is evident from the four plots, the SCGF of the log-density reflects this property in contrast to the SCGF of the density which renders the latter unsuitable.

Fig. 5 compares the measurements to the theoretical result for the SCGF obtained from a Legendre transformation of the rate function according to equation (6). The predictions are expected to be in good correspondence with the measurements if the SCGF is stable against changes in the variance. Again, the log-density clearly improves the range of predictions.
Figure 4. Comparison of the measured SCGF $\varphi_\rho(\lambda)$ (top) and $\varphi_\mu(\lambda)$ (bottom) at redshift $z = 0$ for radii $R$ (in Mpc$/h$) (left) and for redshifts from $z = 0$ to $z = 2.33$ with the radius $R = 10$ Mpc$/h$ (right) as labeled. The considerably weaker dependence of $\varphi_\rho(\lambda)$ on the radius $R$ and the redshift $z$ (and hence the variance $\sigma^2$) shows visually that it is better justified to use the low variance limit result for $\varphi_\mu(\lambda)$ also for finite variances instead of doing so for $\varphi_\rho(\lambda)$. Note however that the same value $\lambda$ corresponds to different densities depending on whether one considers $\varphi_\rho(\lambda)$ or $\varphi_\mu(\lambda)$. This is illustrated in Fig. 6 using the saddle-point approximation.

Figure 5. The ratio of the measured SCGF and the prediction from the Legendre transform of the rate function (6) plotted as a function of $\rho$ with the help of the saddle-point approximation $\lambda = \psi'$ for the density (dashed lines) and the log-density (solid lines). Clearly, the residuals for the log-density are within 5% for $\rho \in [0.5, 2.5]$ while those for the density show besides criticality above $\rho_c \approx 2.5$ also significant deviations for $\rho < \rho_c$.

Figure 6. Comparison of the saddle-point approximation for the SCGF showing $\rho = \varphi'_\rho(\lambda)$ (dashed lines) and $\rho(\mu) = \exp(\varphi'_\mu(\lambda))$ (solid lines) at redshift $z = 0$ for $R$ in Mpc$/h$ as labeled. The horizontal asymptotes of the derivative of the cumulant generating function $\varphi'$ at large $\lambda$ demonstrate that the Legendre transform will not be possible through that range of values.

of applicability of the above-described theoretical construction.

Fig. 6 shows the density which can be associated to the argument of the measured SCGF $\varphi(\lambda)$ from Fig. 4 by using the saddle-point approximation to obtain $\mu = \varphi'_\mu(\lambda)$ and from there $\hat{\rho} = \exp \mu$ or directly $\hat{\rho} = \varphi'_\mu(\lambda)$. The saturation in the density as a function of $\lambda$ signals up to which maximum density the saddle-point approximation can be applied in principle.
4 CONSTRUCTIONS OF THE DENSITY PDFS

We are now in position to build explicit density PDFs following the method sketched in Section 2.1.

4.1 One cell PDF

Fig. 7 shows the density PDF obtained from the numerical integrations equations (8) and (10) and the saddle-point approximations equations (9) and (11) in comparison to the measurement from the simulation including the corresponding residuals. It shows that if the log-density is used, the saddle-point approximation (11) (shown as blue dotted lines) becomes accurate over a wide range of densities \( \rho \in [0.5, 5] \) when compared to simulations, and coincides with the numerical integration for the log-density equation (10) (shown as blue solid lines) for all densities.

This success is the main result of the present work, as criticality is avoided for the relevant densities when the log-density is considered. It is to be contrasted with the case of the density where the saddle-point approximation equation (9) (shown as dashed red lines) is only applicable in the range \( \rho \in [0.5, 1.5] \) and a more demanding numerical integration in the complex plane must be implemented (shown as red solid lines) to evaluate the PDF using equation (8) as shown in Fig. 2 in Bernardeau, Pichon & Codis (2014).

4.1.1 Ensuring normalization

Since the saddle-point method yields only an approximation to the exact PDF, the PDF obtained from equation (9) has to be normalized \( \hat{P}_R(\hat{\rho}) = P_R(\hat{\rho})/\int P_R(\hat{\rho})\,d\hat{\rho} \). Furthermore, when mapping a PDF for the log density \( \mu \) with zero mean \( \langle \mu \rangle = 0 \) to the one for a density using equation (11), we have to consider the normalized density \( \hat{\rho} = \rho/\langle \rho \rangle = \exp \mu/\langle \exp \mu \rangle \) in order to enforce \( \langle \hat{\rho} \rangle = 1 \). Hence, the final PDF is obtained from equation (11) as

\[
\hat{P}_R(\hat{\rho}) = P_R \left( \hat{\rho} \cdot \frac{\int \hat{\rho} P_R(\hat{\rho})\,d\hat{\rho}}{\int P_R(\hat{\rho})\,d\hat{\rho}} \right)^{\frac{1}{2}}. \tag{24}
\]

4.1.2 Adjusting the variance

The key parameter in the prediction of the PDF is the value of the variance at the pivot scale. In practice, a possible strategy is to treat it as a free parameter to be adjusted to the observations. But in principle, the variance \( \sigma^2 \) can also be predicted by linear theory

\[
\sigma^2(R) = \int \frac{d^3k}{(2\pi)^3} c_{\text{lin}}(k) W_{3D}(kR)^2, \tag{25}
\]

where \( W_{3D}(k) \) is the shape of the top-hat window function in Fourier space,

\[
W_{3D}(k) = 3\left(\frac{\pi}{2}\right)^{3/2} J_{3/2}(k) \tag{26}
\]

and \( J_{3/2}(k) \) the Bessel function of the first kind of order 3/2.

In Table 1 we show a comparison between the values for the variance depending on whether it is predicted by
Large-deviation statistics of the log-density

| R=10 Mpc/h | $\sigma_{\text{lin}}^2$ | $\sigma_{\text{sim}}^2$ | $\sigma_{\text{sim}+\mu}^2$ |
|-----------|----------------|----------------|----------------|
| z=0.97    | 0.214          | 0.192          | 0.226          |
| z=0.65    | 0.286          | 0.247          | 0.305          |
| z=0.0     | 0.470          | 0.418          | 0.607          |
| z=0.0     | 0.396          | 0.305          | 0.242          |

Table 1. Comparison of variances between linear theory $\sigma_{\text{lin}}^2$, measurements in the simulation for the log-density $\sigma_{\text{sim}}^2$ and density $\sigma_{\text{sim}+\mu}$ and the mapping $\sigma_{\text{sim}+\mu}$ from equation (20).

Figure 8. Residuals for the measured PDF compared to two predictions for the log density using the measured $\sigma_{\text{sim}}^2$ (red) or the linear result $\sigma_{\text{lin}}^2$ (green) for two different redshifts as indicated. The value of $\sigma^2$ used here are extracted from table 1. Note that green error bars have been shifted along the x-axis by 0.03.

linear theory for a smoothing scale of $R = 10$ Mpc/h and a spectral index $n_s = -1.576$ or measured in the simulation for either $\mu$ or $\rho$. Note that, we also state the result from converting $\sigma_{\text{sim}}^2$ to $\sigma_{\text{sim}+\mu}$ using equation (20) together with the tree-level perturbation theory result for the third reduced cumulant of the log-density $S^3_{\text{tree}}(\mu) = S^3_{\text{tree}}(\rho) - 3$.

Finally, in Fig. 8 we compare results obtained for the PDF for the log density using the saddle-point approximation depending on whether the linear variance is used for $\mu$ or the variance is measured from the simulation. Note that, while the linear prediction for the variance makes the model fully predictive without any free parameter, it systematically higher (around 10-15%) than the measured value, hence the prediction for the PDF is correspondingly not as accurate.

4.1.3 Large density tail of the PDF

Using the saddle-point approximation for the log density, equation (11), we can straightforwardly obtain the large density tails of the PDF as

$$P_R(\hat{\rho}) \propto 6(\exp[(n_s + 3)\nu]/(n_s + 3))^2 \exp\left[-\frac{\nu^2(\hat{\rho}^2 + 1)\hat{\rho}^2 - \nu^2 - 3}{2\sigma^2_{\text{lin}}(\hat{\rho})}\right].$$

Equation (27) is surprisingly simple and general w.r.t. the parameters of the theory, in contrast to the analytical asymptotic around the critical point $\hat{\rho}_c$ presented in Bernardeau, Pichon & Codis (2014), equation (45). In particular, it shows explicitly how fitting the rare event tail of the PDF allows us to estimate $\nu$ and accordingly quantify possible modifications of gravity.

4.2 The 2-cell log density PDF saddle

Let us now explore the two-cell PDF $P_R(\hat{\rho}_1, \hat{\rho}_2)$ in the saddle approximation limit; this is a straightforward generalization of equation (9) (see Bernardeau, Codis & Pichon 2015, for the general expression of the 2-cells PDF)

$$P_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2) = \exp\left[-\sqrt{\frac{2\pi}{\hat{\rho}_1, \hat{\rho}_2}} \det\left[\frac{\partial^2\Psi_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}{\partial \hat{\rho}_1 \partial \hat{\rho}_2}\right]ight].$$

If the densities $\{\hat{\rho}_1, \hat{\rho}_2\}$ are used as variables, the issue of criticality for the Hessian

$$\det\left[\frac{\partial^2\Psi_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}{\partial \hat{\rho}_1 \partial \hat{\rho}_2}\right] = 0$$

becomes more severe compared the one-cell case where the saddle-point approximation broke down above a critical density. As demonstrated in the left panel of Fig. 9 there is a roughly elliptical critical boundary $\{\hat{\rho}_1, \hat{\rho}_2\}$ beyond which the saddle-point method breaks down. Since the slope, given by the difference between the central and the overall density, is much more restricted, this suggests to apply the logarithmic transform not to the densities individually but to their difference and sum.

A suitable and physically motivated choice for the difference is a mass-weighted one which ensures a well-behaved logarithm as long as the no-shell crossing condition $R_1^2 \hat{\rho}_2 - R_2^2 \hat{\rho}_1 > 0$ is satisfied. This suggest to perform the following logarithmic transform of the sum and difference of mass

$$\mu_1 = \log (r^3 \hat{\rho}_2 - \hat{\rho}_1),$$
$$\mu_2 = \log (r^3 \hat{\rho}_2 - \hat{\rho}_1),$$

where the relative shell thickness is $r = R_2/R_1$ and the no-shell crossing condition enforces $\mu_2$ to be real. The PDF $P(\hat{\rho}_1, \hat{\rho}_2)$, or equivalently $P(\rho, s)$, of the PDF of the inner density $\rho = \hat{\rho}_1$ and slope $s = (\hat{\rho}_2 - \hat{\rho}_1)/(r - 1)$, can then be approximated via a saddle-point approximation by

$$P_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2) = \exp\left[-\sqrt{\frac{2\pi}{\hat{\rho}_1, \hat{\rho}_2}} \det\left[\frac{\partial^2\Psi_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}{\partial \mu_1 \partial \mu_2}\right]\right],$$

which can explicitly be rewritten as

$$P_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2) = \frac{\exp\left[-\sqrt{\frac{2\pi}{\hat{\rho}_1, \hat{\rho}_2}} \det\left[\frac{\partial^2\Psi_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}{\partial \mu_1 \partial \mu_2}\right]\right]}{\sqrt{\rho_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}},$$

with

$$p_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2) = \det\left[\frac{\partial^2\Psi_{R_1,R_2}(\hat{\rho}_1, \hat{\rho}_2)}{\partial \mu_1 \partial \mu_2}\right]\left(\det\left[\frac{\partial \mu_1}{\partial \rho_1}\right]\right)^2$$

$$= \frac{1}{2\pi^3} \left(\frac{\Psi_{\rho_2, \rho_2} - \Psi_{\rho_1, \rho_1}}{2}\right) + \frac{1}{2\pi^3} \left(\frac{\Psi_{\rho_2, \rho_1} + \Psi_{\rho_1, \rho_2}}{2}\right)$$

$$= \frac{1}{2\pi^3} \left(\frac{\Psi_{\rho_2, \rho_2} - \Psi_{\rho_1, \rho_1}}{2}\right) + \frac{1}{2\pi^3} \left(\frac{\Psi_{\rho_2, \rho_1} + \Psi_{\rho_1, \rho_2}}{2}\right),$$

(30)
\[
\text{Nbody} = \text{slope} \quad \text{Log} P(s) = s \cdot \text{slope} \quad \text{P}(s) = \text{P}(\rho, s) - \text{P}(\rho) \quad \text{Contours are displayed for Log P}(\rho, s) = 0, -1/2, -1, \ldots, -3. \quad \text{The grey solid line is the no-shell crossing limit s > } -10(1 - r^3), \quad \text{the red solid line is the critical line for the log-mass saddle approximation while the purple solid line is the critical line for the density saddle approximation.}
\]

with \(\Psi_1\) and \(\Psi_2\) denoting partial derivatives with regard to \(\rho_1\) and \(\rho_2\) respectively.

This change of variables allows to get analytical approximations valid for a wide range of densities and variances. In particular, for a variance \(\sigma = 0.48\), the right panel of Fig. 9 shows that the critical line (in red) only excludes a marginal fraction of the \(\rho - s\) plane (between the red and the grey lines) which has very little weight \((\mathcal{P} \approx 0\) in those regions). The full joint PDF of concentric densities and slopes computed from equation (30) is also shown in Fig. 9 while Fig. 10 uses the two-dimensional knowledge of the PDF to predict the PDF of the slope in subregions (under-dense, over-dense or unconstrained inner cells). The agreement between measurements and the analytical predictions given by equation (30) is remarkably good, even better than the numerical integration of Bernardeau, Codis & Pichon (2015), which probably suffers from numerical inaccuracies in the rare event tails of the distribution. The success of this analytical approach is to be contrasted with the severely limited range of validity of the saddle-point approximation of the density PDF illustrated in the left panel of Fig. 9.

5 CONCLUSION

5.1 Summary

The large deviation principle allows us to make simple and accurate predictions for the cumulants of the distribution of the density within concentric shells based on spherical collapse dynamics. Using the log density considerably extends the regime where the PDF derived from the saddle-point approximation matches the exact PDF because it remedies the problem of criticality reported before.
In particular, the simple analytic model is shown to be able to match the PDF of the density for all densities when compared with a numerical integration in the complex plane. The result for the log-density can be easily linked to the PDF of the density as a one-line approximation, equation (11) and also yields excellent results over a large range of density values when compared to measurements from N-body simulations as illustrated in Fig. 7. In particular, this expression gives immediate access to the rare event tail of the density PDF for large positive densities. The two cells joint PDF of the log density was also presented in the saddle approximation limit. The mass weighted logarithmic mapping performed according to equation (29) yields also an analytic PDF and works very well, making almost the entire space of density and slope \( \{ \rho, s \} \) accessible as shown in Fig. 9.

The origin of the success of the log-density lies in the applicability of its saddle-point approximation and is supported by the quality of the Ansatz corresponding to equation (7), as the cumulants of the log transformed field depend more weakly on their (finite) variance, as illustrated in Fig. 2. This can also render tree-level perturbation theory in the log density more successful in predicting reduced cumulants of the density.

5.2 Perspectives for Dark Energy

Statistics for densities in concentric shells will prove very useful in upcoming surveys as they allow us to study the clustering of peaks (or voids) in the mildly non linear regime (\( \sigma \sim 1 \)) and serve as a statistical indicator to test gravity and dark energy models and/or probe key cosmological parameters in carefully chosen subsets of surveys.

A clear asset of the analytical saddle approximation is that it provides means of simply probing the variation of counts in cells for arbitrary initial power spectra and spherical collapse models, which is clearly of interest in the context of dark energy/modified gravity investigations. In particular, it has to be noted that unlike the numerical integration in the complex plane given by equation (8), the saddle-point method equations (11) in the one-cell case and (30) in the two-cell configuration do not require an analytical linear power spectrum \( P_{\text{lin}}(k) \). In practice, it will allow us to quantify very accurately the cosmological information contained in concentric cell observables. However, this is beyond the scope of this paper and therefore left for future works. For a foretaste of concrete applications we refer to Codis et al. (2016) where a proof of principle for constraining dark energy is provided and the accompanying code LSSFAST\(^6\) to compute density PDFs for arbitrary initial power spectra.

This formalism together with the log transformations could also be directly extended to the joint log density-velocity field divergence statistics, or more generally to any observable which can be expressed, not necessarily linearly, in terms of the densities in concentric cells. In order to make the present formalism ready-to-use for counts-in-cell determined from real datasets, galaxy bias and redshift space distortions have to be taken into account. The complications arising from redshift space distortions could possibly be circumvented by applying the formalism to projected cells with cylindrical symmetry corresponding to photometric redshift surveys. For first results regarding the effects of spatial correlations between cells at finite distance, see Codis, Bernardeau & Pichon (2016).

APPENDIX A: PATH INTEGRAL DERIVATION

Let us present an alternative derivation of the theoretical construction that yields the PDF $P_R(\hat{\rho})$. In fact, the steepest decent method can be used to compute the cumulant generating function in terms of a Legendre transform of a function defined in terms of the initial density field. Recall first that the statistical properties of $\hat{\rho}$ are fully encoded in its moment generating function

$$M_R(\lambda) = \langle \exp(\lambda \hat{\rho}) \rangle = \int d\rho \ P_R(\hat{\rho}) \exp(\lambda \hat{\rho}) , \quad (A1)$$

where $P_R(\hat{\rho})$ is the PDF of having density $\hat{\rho}$ in $S$. The moment generating function is related to the cumulant generating function, $\phi_R(\lambda)$, through

$$M_R(\lambda) = \exp[\phi_R(\lambda)] . \quad (A2)$$

Now it is always possible to re-express formally any ensemble average such as equation (A1) in terms of the statistical properties of the initial density field $\tau$, so that we can formally write

$$\exp[\phi_R(\lambda)] = \int d\tau \ P_R(\tau) \exp(\lambda \hat{\rho}(\tau)) . \quad (A3)$$

As the present-time density $\hat{\rho}$ can arise from different initial contrasts $\tau$, the above-written integral should therefore be understood a path integral over all the possible paths from initial conditions to present-time configuration, with measure $D\tau$ and known initial statistics $P(\tau)$. Let us assume here that the initial PDF is Gaussian so that,

$$P_R(\tau) d\tau = \frac{\exp[-\Psi_R(\tau)]}{\sqrt{2\pi\sigma^2(\tau)}} d\tau , \quad (A4)$$

with $\Psi_R$ then a quadratic form

$$\Psi_R(\tau(\hat{\rho})) = \frac{1}{2\sigma^2(\tau)} \tau(\hat{\rho})^2 . \quad (A5)$$

In the regime where the variance of the density field is small, equation (A3) should be dominated by the path corresponding to the most likely configurations (or in the language of LPD the least unlikely of all unlikely configurations). As the constraint is spherically symmetric, this most likely path should also satisfy spherical symmetry. It is therefore bound to obey the spherical collapse dynamics. Within this regime equation (A3) becomes approximatively

$$\exp[\phi_R(\lambda)] \simeq \int d\tau \ P_R(\tau) \exp(\lambda_\text{SC}(\tau)) , \quad (A6)$$

where the most likely path, $\hat{\rho} = \zeta_\text{SC}(\eta, \tau)$ is the one-to-one spherical collapse mapping between one final density at time $\eta$ and one initial density contrast as already described. Putting equation (A4) into equation (A6), the integration on the r.h.s. of equation (A6) can now be carried by using a steepest descent method, approximating the integral as its most likely value, where $\phi_R(\lambda) = \lambda \hat{\rho} - \Psi_R(\tau)$ is stationary. If $\Psi_R(\hat{\rho})$ is convex, then the Legendre transform is involutive, what implies that $\Psi_R(\hat{\rho})$ is the Legendre transform of $\phi_R(\lambda)$, where $\rho$ is determined implicitly by the stationary condition

$$\Psi_R(\hat{\rho}) = \lambda \hat{\rho} - \phi_R(\lambda), \quad \lambda = \frac{\partial}{\partial \rho} \Psi_R(\hat{\rho}) . \quad (A7)$$

Equation (A7) is of course fully consistent with the more general result derived from LDP.

APPENDIX B: SIMULATION

This paper, makes use of a dark matter simulation produced with Gadget2 (Springel 2005). This simulation is characterized by the following $\Lambda$CDM cosmology: $\Omega_m = 0.265,$
$\Omega_{\Lambda} = 0.735$, $n = 0.958$, $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$ and $\sigma_8 = 0.8$, $\Omega_b = 0.045$ within one standard deviation of WMAP7 results (Komatsu et al. 2011), see Fig. B1. The softening length $24$ kpc$^3$/h.

$\sigma_8$ shot. All histograms drawn in this paper are derived from these samples. Note that the cells overlap for radii larger than 10 Mpc/h.

**APPENDIX C: MAPPING CUMULANTS**

In presence of a nonlinear mapping between $\rho$ and $\mu$, such as a logarithmic transformation, cumulants between these two variables follow specific relations that can be computed explicitly in an expansion with respect to the variance. Note that the whole procedure is made complicated because the notion of connected part is itself dependent on the variable under consideration, so that actually

$$\langle \rho^n \rangle_c \neq \langle (\exp \mu)^n \rangle_c$$

when the left hand side is computed with respect to the variable $\rho$ and the right hand side to the variable $\mu$.

The procedure to determine $\langle \hat{\rho}^n \rangle_c$ using the mapping $\rho = \exp \mu$ is the following

(i) Translate the cumulants $\langle \rho^n \rangle_c$ into moments $\langle \rho^n \rangle$ by using the partial Bell polynomials $B_{n,k}$

$$\langle \rho^n \rangle_c = \sum_{k=1}^{n} (-1)^{k-1} (k-1)! B_{n,k} \{ \{ \langle \rho^n \rangle \}^{m=1,\ldots,n} \} .$$

(ii) Rewrite the moments in terms of $\mu$ using $\langle \rho^n \rangle = \langle \exp(n\mu) \rangle = \langle \exp \varphi_\mu(m) \rangle$ and normalize the result $\hat{\rho} = \rho/\langle \rho \rangle$ to enforce $\langle \hat{\rho} \rangle = 1$

$$\langle \hat{\rho}^n \rangle_c = \sum_{k=1}^{n} (-1)^{k-1} (k-1)! B_{n,k} \{ \{ \langle \varphi_\mu(m) \rangle \}^{m=1,\ldots,n} \} / \langle \varphi_\mu(1) \rangle .$$

(iii) Finally, use the cumulant expansion theorem to state the result entirely in terms of cumulants $\langle \mu^n \rangle_c$ or reduced cumulants $S^\mu_n = \langle \mu^n \rangle_c / (\mu^2)^{n-1}$, respectively,

$$\varphi_\mu(m) = \sum_{l=2}^{\infty} \langle \mu^l \rangle_c^{-1} m^l \sum_{l=2}^{\infty} S^\mu_n \langle \mu^{l-1} \rangle_c^{-1} m^l / l! .$$

This leads to the following expression for the reduced cumulants where $\sigma^\mu_n = \langle \mu^2 \rangle_c$

$$S^\mu_n = \frac{1}{\exp \left( \sum_{l=2}^{\infty} S^\mu_n \sigma^\mu_{l-1} \frac{2^{l-1}}{l!} \right) - \exp \left( \sum_{l=2}^{\infty} S^\mu_n \sigma^\mu_{l-1} \frac{2^{l-1}}{l!} \right)} \left( \sum_{l=2}^{\infty} \frac{2^{l-1} \sigma^\mu_{l-1}}{l!} \right) \left( \sum_{l=2}^{\infty} \frac{2^{l-1} \sigma^\mu_{l-1}}{l!} \right)^{-1} \left( \sum_{l=2}^{\infty} \frac{2^{l-1} \sigma^\mu_{l-1}}{l!} \right)^{-1} \left( \sum_{l=2}^{\infty} \frac{2^{l-1} \sigma^\mu_{l-1}}{l!} \right) .$$

One can then consistently expand the expression (C2) up to leading order in $\sigma^\mu_n$. The corresponding results up to the fifth (reduced) cumulant are below, where for simplicity we define $\sigma^\rho_n = \langle \mu^2 \rangle_c$. While the cumulants for the density $\rho$ are given in Fry & Gaztanaga (1993), the reduced cumulants for the normalized density $\hat{\rho} = \rho/\langle \rho \rangle$ used here read

$$S^\rho_3 = (S^\mu_3 + 3) + \sigma^\rho_3 \left( \frac{3}{2} S^\mu_4 + 2 S^\mu_3 - 2(S^\mu_2)^2 + 1 \right) ,$$

$$S^\rho_4 = S^\mu_4 + 12 S^\mu_3 + 16 + \sigma^\rho_4 \left( 2 S^\mu_5 + \frac{45}{2} S^\mu_4 - 3 S^\mu_3 S^\mu_2 - 18(S^\mu_3)^2 + 36 S^\mu_2 + 15 \right) ,$$

$$S^\rho_5 = S^\mu_5 + 20 S^\mu_4 + 15(S^\mu_3)^2 + 150 S^\mu_3 + 125 + \sigma^\rho_5 \left( \frac{5}{2} S^\mu_6 + 48 S^\mu_5 + 24 S^\mu_3 S^\mu_2 + 345 S^\mu_4 + 15 S^\mu_3 S^\mu_2 - 60(S^\mu_3)^3 - 60(S^\mu_2)^2 + 630 S^\mu_2 + 222 \right) .$$

---

**Figure B1.** A Slice through the ΛCDM 500 Mpc/h sampled with 1024$^3$ particles dark matter simulation used throughout here.
