Stress testing $\Lambda$CDM with high-redshift galaxy candidates

A cold dark matter (ΛCDM)-like cosmological models share a similar basic assumption: baryons and dark matter are well mixed at very early times, and as baryons collapse into dark matter haloes, the maximum amount of baryonic material within a halo will be equal to $M_\star = f_b M_{\text{halo}}$ where $f_b = \Omega_b/\Omega_m$ is the cosmic baryon fraction. This, in turn, bounds the total stellar content of a dark matter halo: $M_\star (M_{\text{halo}}) \leq M_b (M_{\text{halo}})$. I show how this simple relation can be used as a stringent test of either cosmological models with minimal assumptions about galaxy formation, or the reliability of photometric selection and physical characterization of high-redshift galaxy candidates. My analysis is in many ways similar to that of Behroozi and Silk, who connected cumulative number densities of dark matter haloes to high-redshift galaxy stellar mass functions (see also Steinhardt et al.), although I also consider the maximal cumulative stellar mass density allowed in ΛCDM. The question of the consistency of stellar mass functions and the underlying cosmological dark matter halo mass functions has become considerably more urgent with the release of the first data from the James Webb Space Telescope (JWST), and with it, a swarm of high-redshift galaxy candidates.

**Assumptions**

I adopt the base ΛCDM model of the Planck Collaboration, which assumes no spatial curvature and initial conditions that are Gaussian and adiabatic, as the standard cosmological model. I use best-fit values for cosmological parameters based on the plik TT,TE,EE + lowE + lensing likelihood applied to the full mission data. The relevant parameters and values for this work are the present-day Hubble constant, $H_0 = 67.32 \text{ km s}^{-1} \text{Mpc}^{-1}$; the $z = 0$ density parameter for matter, $\Omega_m = 0.3158$ (which includes baryons, dark matter and non-relativistic neutrinos); the slope of the primordial power spectrum of density fluctuations, $n_s = 0.96605$; the root mean square (r.m.s.) amplitude of the linear matter power spectrum at $z = 0$ as measured in spheres of radius 8 $h^{-1}$ Mpc, $\sigma_8 = 0.8120$; and the cosmic baryon fraction, $f_b = \Omega_b/\Omega_m = 0.156$ (ref. 12).

With these values, the linear matter power spectrum is specified at all times relevant for structure formation. The non-linear density field, home to the dark matter haloes that host galaxies, must be computed numerically. However, a long line of research starting with Press and Schechter has been devoted to connecting the abundance of dark matter haloes as a function of redshift and mass to the underlying linear matter power spectrum. In what follows, I use the Sheth and Tormen dark matter halo mass function $dn(M,z)/dM$—the number of dark matter haloes of mass $M$ per unit mass per unit co-moving volume at redshift $z$—to compute the co-moving number density of haloes above a given halo mass threshold,

$$n(> M_{\text{halo}}, z) = \int_{M_{\text{halo}}}^{\infty} dM \frac{dn(M,z)}{dM}$$

and the co-moving mass density in haloes more massive than $M_{\text{halo}}$. Early data from the James Webb Space Telescope (JWST) have revealed a bevy of high-redshift galaxy candidates with unexpectedly high stellar masses. An immediate concern is the consistency of these candidates with galaxy formation in the standard ΛCDM cosmological model, wherein the stellar mass ($M_\star$) of a galaxy is limited by the available baryonic reservoir of its host dark matter halo. The mass function of dark matter haloes therefore imposes an absolute upper limit on the number density $n(> M_\star, z)$ and stellar mass density $\rho_\star(> M_\star, z)$ of galaxies more massive than $M_\star$ at any epoch $z$. Here I show that the most massive galaxy candidates in JWST observations at $z = 7$–10 lie at the very edge of these limits, indicating an important unresolved issue with the properties of galaxies derived from the observations, how galaxies form at early times in ΛCDM or within this standard cosmology itself.

In the left panel, as those galaxies must reside in host halo of mass $M_{\text{halo}}$, the cumulative co-moving number density that is, at most, the number density shown in the left panel, as those galaxies must reside in host halo of mass $M_{\text{halo}} = M_*/f_\epsilon$.

The cumulative co-moving number density corresponding to an observed $M_*$ will probably be (much) smaller than is indicated here, as the curves are placed on the plot by assuming the physically maximal $\epsilon = 1.0$. For smaller values of $\epsilon$, the curves in each panel move down relative to the points by a factor of $\epsilon$ (as indicated by the black downward-facing arrows). The right panel demonstrates that even for the most conservative assumption of $\epsilon = 1.0$, the data points correspond to very rare peaks in the density field, implying a limited baryonic reservoir that is in tension with the measured stellar masses of the galaxies.

These translate directly to upper limits on the statistics of galaxies through the straightforward assumption that the largest stellar content a halo can have, given its cosmic allotment of baryons, is $M_{\star, \text{max}} = f_\star M_{\text{halo}}$. More generally, we may write $M_{\star} = f_\star M_{\text{halo}}$ with $\epsilon \leq 1.0$ being the efficiency of converting baryons into stars.

The cumulative co-moving number density of dark matter haloes more massive than $M_{\text{halo}}$, thus sets an upper limit on the co-moving number density of galaxies more massive than $M_*$,

$$n_{\text{gal}}(> M_*, z) \leq n_{\text{halo}}(> M_*/f_\star).$$

Similarly, the cumulative co-moving density of collapsed mass sets an upper limit on the density of collapsed baryons, $\rho_0(> M_{\text{halo}}) = f_\star \rho_{\text{m}}(> M_{\text{halo}})$, which in turn strictly bounds the co-moving number density of stars contained in haloes more massive than $M_{\text{halo}}$,

$$\rho_\star(> M_{\text{halo}}) \leq f_\star \rho_{\text{m}}(> M_{\text{halo}}).$$

and the density of stars contained in galaxies above a given $M_*$,

$$\rho_\star(> M_*) \leq f_\star \rho_{\text{m}}(> M_*/f_\star).$$

### Results

The left panel of Fig. 1 shows the relationship between the maximal inferred stellar mass for a given $M_{\text{halo}}, M_*=f_\star M_{\text{halo}}$, (that is, assuming the maximal $\epsilon = 1.0$) and redshift $z$ for fixed cumulative co-moving halo number densities ranging from $10^{-10}$ Mpc$^{-3}$ (light grey) to $10^{-2}$ Mpc$^{-3}$ (yellow). The curves evolve rapidly with redshift, with the maximal stellar mass corresponding to a fixed cumulative co-moving halo number density increasing by three orders of magnitude from $z=20$ to $z=5$. This rapid rise indicates that the mass reservoir available for the most massive galaxies increases quickly with redshift at fixed halo number density. The two most massive high-redshift galaxy candidates from the Labbé et al. (hereafter L23) sample, at $z=7.5$ ($M_*=10^{11} M_\odot$) and $z=9.1$ ($M_*=10^{10.5} M_\odot$), are shown as blue stars. These objects are unexpectedly massive, with stellar content reflective of haloes that have cumulative co-moving number densities no higher than $10^{-5.2}$ Mpc$^{-3}$ (if $\epsilon=1.0$); for $\epsilon=0.32$ (0.10), the implied number density is $10^{-6}$ ($10^{-8}$) Mpc$^{-3}$. By comparison, the candidates were found in a survey of 38 arcmin$^2$, a volume of $V = 10^3$ Mpc$^3$ at each of the redshift bins $7 < z < 8.5$ and $8.5 < z < 10$—considered by L23.

The right panel of Fig. 1 recasts the issue in terms of the scarcity of systems as measured by cumulative mass density. In extended Press–Schechter models, the peak height $\nu(\delta_\text{halo}, z) = \delta_c/\sigma(z)$ of an object—where $\delta_c=1.7$ is the linear collapse threshold and $\sigma^2(z)$ is the variance of the linear density field at redshift $z$ smoothed on a scale containing an average mass of $M_{\text{halo}}$—is a measure of the fraction of mass in the Universe contained in virialized objects more massive than $M_{\text{halo}}$ at redshift $z$. Typical haloes at $z=0$ have $\nu=1$, which corresponds to 24% of the mass in the Universe residing in haloes at least that massive; larger values of $\nu$ indicate increasingly massive and therefore rare peaks in the density field at that epoch. The co-moving baryon density for each peak height in the figure is given in the legend; multiplying this number by the volume of a survey gives the total amount of baryons contained above the mass corresponding to that peak height and redshift. The L23 galaxies have peak heights of at least $\nu=4.5$ (assuming $\epsilon=1.0$), meaning that, at most, a fraction $6.2 \times 10^{-5}$ of the baryons in the Universe are contained in haloes massive enough to host these galaxies. For reference, $\nu=4.5$ at $z=0$ corresponds to $M_{\text{halo}}=5 \times 10^{14} M_\odot$. Adopting more reasonable efficiencies of $\epsilon=0.32$ or 0.10 results in rarer peaks with $\nu=5.4$ or 6.4.

Figure 2 shows the cumulative stellar mass density reported by L23 at $z=9$ (left) and $z=7.5$ (right). The data, which come from individual
Massive objects, lie at the extreme of ΛCDM expectations, even in the most optimistic scenario: at both redshifts, the measurements lie at the theoretical limit of ρₐ(>Mₘ) = fᵦρ₀(<Mₘfₒ), implying physically implausible values of ε(z = 9) = 0.99 and ε(z = 7.5) = 0.84. When considering the 1σ error (which incorporates uncertainties from Poisson fluctuations and sample variance added in quadrature), the data become marginally consistent with the available baryon reservoirs for an efficiency of ε(z = 9) ≥ 0.57, which is probably an unrealistically high value. Assuming a more plausible value of ε = 0.10 or 0.32 yields a strong discrepancy with ΛCDM expectations at both redshifts, even when considering observational uncertainties.

**Discussion**

The first glimpse of high-redshift galaxy formation with JWST has revealed surprisingly massive galaxy candidates at early cosmic times. These systems provide a way to test a bedrock property of the ΛCDM model (or alternately, assumptions in derivations of stellar masses or the viability of high-redshift galaxy candidates): the stellar content of haloes should not exceed the available baryonic material in those haloes. This requirement does not rely on assumptions such as abundance matching, but rather is simply a statement about the distribution of virialized mass in the Universe as a function of redshift and the baryonic reservoirs associated with those virialized haloes: galaxies of mass Mₘ can only form if haloes of mass Mₒ/εₙ can have formed. It is also more stringent than the requirement that the observed galaxy ultraviolet luminosity function not exceed the theoretical maximum coming from a nearly instantaneous (10 Myr) conversion of a halo’s full baryonic reservoir into stars, as it is an integral constraint as opposed to a differential one. The massive, high-redshift galaxy candidates catalogued in L23 lie near or at the stellar mass density constraint in ΛCDM.

There are several sources of observational uncertainty that enter these results. The flux calibration of NIRCam is continually being updated; L23 use calibrations that take into account updated detector offsets that are not yet part of the official JWST reduction pipeline (see, for example, Boyer et al. for related discussions of empirical point spread function modelling for JWST). With NIRCam photometry, a Balmer or 4,000 Å break at z = 5 can be mistaken for a Lyman α break at z ≥ 12 (ref. 18); the L23 sample was selected to contain both Lyman and Balmer breaks, however, and is at low enough redshift (relative to z = 15 sources) that NIRCam filters can typically exclude z = 5 photometric solutions. The resulting photometric redshift estimates have single, narrow (αₜ = 0.25) peaks. The masses of the galaxies are computed using the median of four methods for fitting the photometry (see L23 for details) and assume a Salpeter initial mass function. Different assumptions about the photometry (in particular, properties of nebular emission lines or the presence of an accreting supermassive black hole) or initial mass function could affect the derived stellar masses. The mass of the candidate at z = 7.5 was also corrected for the possibility of amplification by mild gravitational lensing; this effect is estimated by L23 to be 0.15 dex, and the reported mass (and stellar mass density) of this object are therefore reduced by this amount to compensate. The error bars in Fig. 2 include errors in the volume estimates coming from both sample variance and Poisson noise, with the latter always being dominant in the regime considered here. The discrepancy between the observed high-redshift galaxy candidates and ΛCDM expectations is robust to uncertainties in cosmological parameters in the base ΛCDM model: the precision on each of the relevant parameters is at the ≲1% level. Intriguingly, extensions to the base ΛCDM with enhanced values of αₜ, n, and the physical matter density ΩₐH²—such as some early dark energy (EDE) models whose aim is to resolve the Hubble tension—predict earlier structure formation and a higher abundance of haloes at fixed mass at high redshift, which would enhance the baryonic reservoir available for forming early massive galaxies. Taking the best-fit EDE parameters from Smith et al., the cumulative co-moving baryonic density contained in galaxies more massive than Mₘ = fₒMₘhalo for the most massive L23 galaxy candidate at z = 9.1 is a factor of 3.1 larger in EDE than in base ΛCDM, which is...
non-negligible; the L23 data points would then lie at $\epsilon = 0.74$ instead of $\epsilon = 0.99$. However, this EDE cosmology is in stronger tension with values of $S_8 = \sigma_8 \sqrt{\Omega_{m,0}/0.3}$ measured at low redshift and predict that the Universe is $\approx 13$ billion years old (as opposed to 13.8 billion years in the base ΛCDM model), which is in moderate tension with the measured ages of ultra-faint galaxies and globular clusters.

At the redshifts studied here, $z = 7–10$, the Sheth–Tormen mass function overestimates the abundance of massive haloes by 20–50% relative to numerical simulations $^{24,25}$, meaning their true abundance at high redshift is probably lower than the Sheth–Tormen prediction and the constraints derived here are conservative. However, the lack of detailed comparisons between theory and simulations at high redshifts and high masses points to the importance of continued theoretical work in understanding the universality and applicability of halo mass function parameterizations in regimes relevant for JWST observations (and other forthcoming observatories).

The tension discussed in this paper is straightforward: the masses measured by L23 are only consistent with expectations from the standard cosmological model at the reported redshifts if star formation in the earliest phases of galaxy formation is incredibly efficient ($\epsilon \geq 0.57$). In the low-redshift Universe, such efficiencies are never seen, with $\epsilon \leq 0.2$ for all galaxies. The theoretical expectation is that efficiencies do indeed increase at high redshift $^{12}$, although $\epsilon \geq 0.57$ is still highly extreme and probably implausibly high. If the explanation of the L23 galaxies is indeed a very high star formation efficiency, it implies that the star formation histories of such systems must rise steeply with time, following the behaviour of the baryon reservoirs inside virialized structures in ΛCDM. The results presented here could also be explained if the stellar initial mass function differs substantially from the assumed Salpeter form, the black hole accretion contributes significantly to the galaxies’ emitted light or the volumes currently surveyed turn out to be highly atypical.

If none of these explanations holds up and these massive galaxies are spectroscopically confirmed, they will pose a serious challenge for ΛCDM structure formation with parameters given by Planck Collaboration $^{3}$ because they signify the existence of a larger reservoir of collapsed baryons than is possible in this model. Forthcoming wider field JWST surveys, along with JWST spectroscopy of massive galaxy candidates, should be able to quickly confirm or refute the existence of this tension. Furthermore, the compatibility of any additional high-redshift galaxies or galaxy candidates discovered in JWST observations with ΛCDM expectations can be assessed in a straightforward way via Fig. 1. If analysis of JWST data continues to reveal the presence of strikingly massive galaxies at very early cosmic epochs, more exciting surprises lie ahead for the fields of galaxy formation and cosmology.

### Data availability
Data from L23, including stellar mass estimates and photometric redshifts, are available at [https://github.com/ivolabbe/red-massive-candidates](https://github.com/ivolabbe/red-massive-candidates); this paper uses data from sample revision 3.2207.12446.ecsv, commit 59fbbfa (from 2 January 2023).

### Code availability
All calculations that go into the figures in this paper are publicly available at [https://github.com/mrbk/JWST_MstarDensity](https://github.com/mrbk/JWST_MstarDensity).
