Simple Summary: Farm animals are constantly exposed to pathogenic microorganisms, which can lead to bacterial, as well as secondary infections caused by viruses. For this reason, vaccination is used. However, many discussions have been published about the effectiveness of this prophylactic measure. The aim of this study was to evaluate the influence of fermented feed on non-vaccinated (NV) and vaccinated with Circovac porcine circovirus type 2 vaccine piglets’ blood parameters, gut microbial composition, growth performance and ammonia emission. The 36-day experiment was conducted using 25-day-old Large White/Norwegian Landrace piglets, which were randomly divided into four groups each comprising 100 piglets (NV piglets fed with soya meal, vaccinated piglets fed with soya meal, NV piglets fed with fermented rapeseed meal and vaccinated piglets fed with fermented rapeseed meal). The results revealed that vaccination, as a separate factor, did not significantly influence piglets’ blood parameters. Finally, rapeseed meal fermented with the selected lactic acid bacteria strains can be used instead of expensive imported soya, because the fermented feed did not cause undesirable changes in piglets’ health and growth performance. Furthermore, the process is more sustainable.

Abstract: The aim of this study was to evaluate the influence of fermented with a newly isolated lactic acid bacteria (LAB) strains combination (Lactobacillus plantarum LUHS122, Lactobacillus casei LUHS210, Lactobacillus farraginis LUHS206, Pedicoccus acidilactici LUHS29, Lactobacillus plantarum LUHS135 and Lactobacillus urenus LUHS245) feed on non-vaccinated (NV) and vaccinated with Circovac porcine circovirus type 2 vaccine (QI09AA07, CEVA-PHYLAXIA Co. Ltd. Széll Kálmán u. 5. 1107 Budapest, Hungary) piglets’ blood parameters, gut microbial composition, growth performance
Animals 2020, 10, 1201

and ammonia emission. The 36-day experiment was conducted using 25-day-old Large White/Norwegian Landrace (LW/NL) piglets, which were randomly divided into four groups with 100 piglets each: $S_{\text{nonV}}$—non-vaccinated piglets fed with control group compound feed; $S_{\text{V}}$—vaccinated piglets fed with control group compound feed; $RF_{\text{nonV}}$—non-vaccinated piglets fed with fermented compound feed; $RF_{\text{V}}$—vaccinated piglets fed with fermented compound feed. Samples from 10 animals per group were collected at the beginning and end of the experiment. Metagenomic analysis showed that fermentation had a positive impact on the Lactobacillus prevalence during the post-weaning period of pigs, and vaccination had no negative impact on microbial communities. Although a higher amount of Lactobacillus was detected in vaccinated, compared with non-vaccinated groups. At the end of experiment, there was a significantly higher LAB count in the faeces of both vaccinated compared to non-vaccinated groups (26.6% for $S_{\text{V}}$ and 17.2% for $RF_{\text{V}}$), with the highest LAB count in the $S_{\text{V}}$ group.

At the end of experiment, the $S_{\text{V}}$ faeces also had the highest total bacteria count (TBC). The $RF_{\text{V}}$ group had a 13.2% increase in total enterobacteria count (TEC) at the end of experiment, and the $S_{\text{V}}$ group showed a 31.2% higher yeast/mould (Y/M) count. There were no significant differences in the average daily gain (ADG) among the groups; however, there were significant differences in the feed conversion ratios (FCR) between several groups: $S_{\text{V}}$ vs. $S_{\text{nonV}}$ (11.5% lower in the $S_{\text{V}}$ group), $RF_{\text{V}}$ vs. $RF_{\text{nonV}}$ (10.2% lower in the $RF_{\text{nonV}}$ group) and $S_{\text{V}}$ vs. $RF_{\text{V}}$ (21.6% lower in the $S_{\text{V}}$ group). Furthermore, there was a significant, very strong positive correlation between FCR and TEC in piglets' faeces ($R = 0.919$, $p = 0.041$). The lowest ammonia emission was in $RF_{\text{V}}$ group section (58.2, 23.8, and 47.33% lower compared with the $S_{\text{nonV}}$, $S_{\text{V}}$ and $RF_{\text{nonV}}$ groups, respectively). Notably, there was lower ammonia emission in vaccinated groups (45.2% lower in $S_{\text{V}}$ vs. $S_{\text{nonV}}$ and 47.33% lower in $RF_{\text{V}}$ vs. $RF_{\text{nonV}}$). There was also a significant, very strong positive correlation between ammonia emission and Y/M count in piglets' faeces at the end of the experiment ($R = 0.974$; $p = 0.013$). Vaccination as a separate factor did not significantly influence piglets' blood parameters. Overall, by changing from an extruded soya to cheaper rapeseed meal and applying the fermentation model with the selected LAB combination, it is possible to feed piglets without any undesirable changes in health and growth performance in a more sustainable manner. However, to evaluate the influence of vaccination and its interaction with other parameters (feed, piglets' age, breed, etc.) on piglets' parameters, additional studies should be performed and methods should be standardised to ensure the results may be compared.

### 1. Introduction

The challenges associated with livestock production become greater each year. This phenomenon is associated with population growth, as well as growing needs for animal-based products. Farms have become bigger, and animals are always exposed to opportunistic and pathogenic microorganisms. Most pathogen infections have a multifunctional influence on the host tissues and cells, and the response to the infection rather than the infection itself results in most of the damage and a general disturbance in physiological processes [1–5]. One consequence of infections on pig production is multisystemic wasting syndrome after weaning. Indeed, it is crucial to ensure piglets health at the earliest stage, because type 2 porcine circovirus (PCV2) leads to multisystemic wasting syndrome after weaning, and co-infection with other pathogens can be lethal [6,7]. Some published findings have indicated the potential participation of PPV2 in clinical diseases. PCV2 can occur as a co-infection with other pathogens in animals afflicted with respiratory disease [8], as well as in the lungs of animals with inflammatory lesions [9]. PCV2 infection leads to metabolic and neurological disorders; the latter cause multisystemic wasting syndrome [10–12]. To improve animal keeping conditions, understanding the interactions between desirable microorganisms and pathogens and reduce the risk of secondary infections is critical.
to develop preventive measures against various diseases. In this study, we hypothesised that, for vaccinated piglets, incorporating antimicrobial strains for feed fermentation can be a very attractive feeding option. Finally, incorporation and biomodification of local feedstock with antimicrobial lactic acid bacteria (LAB) strains can lead to higher value feedstock for farm animal nutrition and improve their conditions. This use can also increase the sustainability of pig farming and reduce dependence on imported soya stock. In this case, natural antimicrobial treatment, e.g., feed fermentation with antimicrobial LAB strains, is also desirable because the genetic divergence of PCV2 continuously increases, and novel subtypes are still emerging [13–15]. PCV2-related diseases are considered multifactorial in the swine industry [7], and they can promote co-infection with other viruses or bacteria [8,9,16]. In addition, co-infection of different viruses complicates the infection status and makes it more difficult to prevent and control the diseases [17]. Vaccines are used to prevent viral infections and antibiotics are used to treat bacterial diseases, but there is a lack of complex tools for prevention of diseases. Furthermore, viruses and bacteria can mutate very quickly, a phenomenon that remains a huge challenge for the livestock industry. Animals are always exposed to the environment, and thus changes in the microorganisms present in the digestive tract should be studied to understand the mechanism of action, which can be associated with vaccination, as well as with the natural antimicrobials, as the microorganisms in the gut strongly influence the immune system and animals’ health.

The aim of this study was to evaluate the influence of fermented with a newly isolated LAB strains combination (\textit{Lactobacillus plantarum} LUHS122, \textit{Lactobacillus casei} LUHS210, \textit{Lactobacillus farraginis} LUHS206, \textit{Pediacoccus acidilactici} LUHS29, \textit{Lactobacillus plantarum} LUHS135 and \textit{Lactobacillus uvarum} LUHS245) feed on non-vaccinated (NV) and vaccinated with Circovac porcine circovirus type 2 vaccine (QI09AA07, CEVA-PHYLAXIA Co. Ltd. Szállás u. 5. 1107 Budapest, Hungary) piglets’ blood parameters, gut microbial composition, growth performance and ammonia emission. This LAB starter combination, with antimicrobial characteristics, was used to ferment local feedstock (rapeseed meal), and the influence of changing from an extruded soya to biomodified rapeseed meal on the parameters of non-vaccinated piglets and those vaccinated with the Circovac PCV2 vaccine was evaluated.

2. Materials and Methods

2.1. LAB Strains Used for Feed Fermentation, Feed Fermentation and Fermented Feed Parameters

The \textit{L. plantarum} LUHS122, \textit{L. casei} LUHS210, \textit{L. farraginis} LUHS206, \textit{P. acidilactici} LUHS29, \textit{L. plantarum} LUHS135 and \textit{L. uvarum} LUHS245 strains were obtained from the Lithuanian University of Health Sciences collection (Kaunas, Lithuania). Our previous studies showed that the above-mentioned strains inhibit various pathogenic and opportunistic microorganisms and are suitable for fermentation of various cereal substrates [18–22], as well for rapeseed meal fermentation [23]. The rapeseed meal, water and LAB strains (equal parts of each strain by volume) suspension (3% from dry matter of feed mass, \textit{v}/\textit{m}), containing 8.9 log\textsubscript{10} colony forming units CFU/mL, was fermented at 30 ± 2 °C for 12 h. The fermentation process involves wheat and rapeseed meal (1:1 ratio). The crude protein content of the rapeseed meal was 33.58%. Fermented feed was composed of 25% fermented rapeseed meal and 25% fermented wheat. This combination contained 23.24% crude protein. The compound feed for all groups contained 19% crude protein, crude fibre—3.15%, crude oil—6.51%, lysine—1.45%, methionine—0.55%, tryptophan—0.26%, threonine—0.93%, Ca—0.90%, total P—0.59% and Na—0.20%. The entire fermented wheat/rapeseed meal mass was divided in two parts: 70% (by mass) was used for piglet feeding, and 30% (by mass) was used as a starter for additional feed fermentation cycles (Figure 1). The detailed fermented feed technology and characteristics are described by Vadopalas et al. [23].
2.2. Animals and Housing

All animal procedures were conducted according to the European Union (EU) Directive of the European Parliament and Council, from 22 September, 2010 [24], on the protection of animals used for scientific purposes and the ‘Requirements for the Keeping, Maintenance and Use of Animals Intended for Science and Education Purposes’, approved by the order of the Lithuanian Director of the State Food and Veterinary Service [25]. The study was conducted at a pig farm in the Klaipeda district (Kontvainiai, Lithuania) and at the Institute of Animal Rearing Technologies, Lithuanian University of Health Sciences (Kaunas, Lithuania). A 36-day experiment was conducted using 25-day-old Large White/Norwegian Landrace (LW/NL) piglets with an initial body weight of 6.9–7.0 kg. Four groups were formed, each with 100 piglets: SV—non-vaccinated piglets fed with control group compound feed; SVN—vaccinated piglets fed with control group compound feed; RFN—non-vaccinated piglets fed with fermented compound feed; RFV—vaccinated piglets fed with fermented compound feed. The weaner piglets were kept at the same conditions in a section with two climate zones. The first had a heated concrete floor (36 °C) and roof on it; the second had plastic piglet floors and optimum ventilated air and temperature for the active period. Drinking water and compound liquid feed were available ad libitum throughout the trial. Antibiotic treatment was not applied.

2.3. Experimental Design and Diets

Samples from 10 animals per group were collected at the beginning and end of experiment. Two groups (SV and RFV) were vaccinated by intramuscular injection with Circovac PCV2 vaccine (inactivated) (QI09AA07, CEVA-PHYLAXIA Co. Ltd. Szállás u. 5. 1107 Budapest, Hungary), which is used to protect pigs against PCV2. The influence of two dietary treatments on vaccinated and non-vaccinated piglets’ parameters were compared. Fermented feed, comprising 500 g/kg of total feed, was included in the diet of treated group beginning at day 25 of life until day 61. Piglets’ growth performance was evaluated by testing all 100 piglets in each group. The basal feed was formulated according to the nutritional requirements prescribed in the Nutrient Requirements of Swine [26]. The feed composition and nutritional value are shown in Table 1. The nutritional value of compound feed was determined according to the analytic methods described by Association of Official Analytical Chemists (AOAC) [27].
Table 1. Diet composition (dry matter 87 %).

| Ingredients (%)                  | Control Group | Treated Group |
|----------------------------------|---------------|---------------|
| Barley                           | 38.45         | 33.25         |

ME—metabolisable energy. 1 Composition of premix per 1 kg of feed: Vitamin A—18,180 IU; vitamin D3—2040 IU; vitamin E—161 mg kg⁻¹; vitamin K3—5.03 mg; thiamine—3.64 mg; riboflavin—9.16 mg; choline chloride—404 mg; pyridoxine—4.60 mg; vitamin B12—0.05 mg; niacin—41 mg; pantothenic acid—22.85 mg; folic acid—1.85 mg; biotin—0.21 mg; Fe—152 mg; Cu—100 mg; Zn—91 mg; Mn—80 mg; I—0.81 mg; Co—0.53 mg; Se—0.30 mg.

2.4. Metagenomics and Microbial Profiling Analysis

Before the experiment, faeces from 25-day old piglets from each group (10 piglets per group) were collected. The same procedure, using 10 piglets per group, was performed at the end of the experiment (day 61 of the piglets’ life). Faecal samples from each of the group were pooled making 4 samples before and 4 samples after the experiment. Therefore, 8 samples representing 4 tested groups (before and after the experiment) were sequenced for microbial profiling. Specimens were kept in DNA/RNA Shield diluted 1:10 (R1100-250, Zymo Research, Irvine, CA USA) at −80 °C before DNA extraction. DNA was extracted with a faecal DNA MiniPrep kit (D6010, Zymo Research, Irvine, CA USA). Library preparation, metagenomic sequencing and taxonomic characterisation of reads was performed as previously described [28]. ZymoBIOMICS Microbial Community Standard (D6300, Zymo Research, Irvine, CA USA) was used as a microbiome profiling quality control. The results of taxonomic classification were visualised using the interactive online platform https://genome-explorer.com.

2.5. Microbiological Analysis of Faecal Samples

Piglets’ faecal samples were collected before and after the experiment, stored in vials (+4 °C) with a transport medium (Faecal Enteric Plus, Oxoid, Basingstoke, UK) and analysed on the same day. Evaluation of the microbiological parameters (LAB, total viable bacteria count [TVC], total...
Animals 2020, 10, 1201

The number of bacterial reads in pig faeces before and after the experiment was quite similar: it varied between 35,000 and 40,000 reads among the groups. The number of species with a prevalence of at least 0.01% from the total amount of bacteria in different groups before the experiment was also similar: it varied from 400 in the RF_{nonV} group to 473 in the S_{V} group. The number of species with
the same prevalence rate at the end of experiment varied from 340 to 387. Although the number of bacterial reads and bacterial composition among the groups was similar, we detected some distinct differences, particularly in the number of lactobacilli.

Before experiment, two bacterial genera—Prevotella and Lactobacillus, had the highest prevalence rates in all groups of pigs; they accounted for more than 40% of the total amount of bacterial composition (Figure 2). The prevalence of Prevotella varied from 21.8% to 38.2%, while Lactobacillus prevalence ranged from 19.9% to 29.7%. The lowest Lactobacillus prevalence was in the RFV group, while the highest was in SnonV group. In all groups, the most prevalent species among Lactobacillus was Lactobacillus amylovorus (Tables S1–S4)). The other most prevalent genera included Barnesiella, Clostridium, Blautia, Faecalibacterium, Roseburia and Eubacterium, which ranged from 1.2% (Eubacterium) up to 3.4% (Barnesiella) in the faeces. Overall, the microbial profiles were similar among all the groups before the experiment (Figure 2), however, it should be mentioned that Bifidobacterium was detected only in two groups—RFnonV and RFV with the prevalence of 4.5% and 1.7% respectively.

At the end of experiment, the microbial profiles had changed depending on the pig group (Figure 3). Overall, the main genera remained similar as before experiment, but there were obvious differences in the Lactobacillus prevalence. The lowest prevalence occurred in faeces from the SnonV group, while the highest was in the RFV group (p ≤ 0.05). In the latter group, lactobacilli were the most abundant bacteria: their prevalence reached 47.9% of the total bacteria, while in the rest of the groups the highest prevalence was Prevotella. When comparing groups with fermented vs. non-fermented feed, pigs that received fermented feed had a notably higher Lactobacillus prevalence compared to pigs fed non-fermented feed. The pigs from non-fermented feed groups had higher Clostridium and Terrisporobacter prevalence (p ≤ 0.05), while the prevalence of other bacterial genera was low overall in all groups.

When comparing non-vaccinated with vaccinated groups, the main differences were also associated with the Lactobacillus prevalence: it was higher in vaccinated compared to non-vaccinated groups (p ≤ 0.05). At the same time, the amount of Prevotella was higher in non-vaccinated groups, although the differences between RFnonV and SnonV groups were small (31.4% vs. 30.2%). The species prevalence and variety at the end of the experiment are presented in Tables S5–S8).

The microbial communities in the pig gut perform a variety of beneficial functions [31]. Previous studies of the gut microbial community have illustrated how populations of constituents are shaped by environmental exposure to microbes, diet, immunological pressures, host genetics and ecological forces within the ecosystem itself [32–34]. Understanding which microbial populations are influenced by fermented feed provides insight into how dietary changes in pigs shape the gut microbiome. Although there have been studies about microbial communities within the gut of healthy pigs, the microbial composition can differ depending on breed, age, place, feed, hygiene conditions and other factors [31,35,36]. This study demonstrated changes in microbial profiles using feed prepared by different technologies within similar groups of animals and the same farm. While the exact mechanism(s) by which vaccination can influence microbial changes within the gut of mammals remains unknown, this study suggests that vaccination has a certain influence, particularly on the number of Lactobacillus spp.
Figure 2. Microbial profiles (prevalence, %) at the genus level in pig faeces before the experiment.
Figure 3. Microbial profiles (prevalence, %) at the genus level in pig faeces after experiment.

Before the experiment, the microbial composition in all groups was very similar, with the highest prevalence for *Prevotella* and *Lactobacillus*, both of which accounted for 56% of the bacterial count. These genera include abundant microorganisms in young weaned healthy pigs [37]. *Prevotella* spp. are usually dominant in pigs’ gut and gradually increase in number with age [38,39]. *Prevotella* spp. are key microbial members of the gastrointestinal tracts of adult animals; they are crucial for the degradation of starch and plant polysaccharides but also have a strong capacity for mucoprotein catabolism [40,41]. *Lactobacillus* spp. are common in both the proximal and distal regions of the porcine digestive tract; they colonise soon after birth [42]. This genus influences intestinal physiology, regulates the immune system and balances the intestinal ecology of the host [43]. In addition, *Lactobacillus* spp. have been known to metabolise carbohydrates, including oligosaccharides and starch, which are fermented in the large intestine to short chain fatty acids by lactobacilli for subsequent utilisation by the pigs [44]. Previous studies have indicated that stress greatly affects the gastrointestinal microbiota: it decreases total *Lactobacillus* populations and thus provides an opportunity for pathogen overgrowth [45]. Such stress
usually occurs during the weaning period. According to the literature, when compared to diarrhoeic piglets, the gut microbiota of healthy piglets has a higher abundance of Prevotellaceae, Lachnospiraceae, Ruminococcaceae and Lactobacillaceae [46]. These data suggest that the gut microbial composition may be used as a biomarker to predict the health status of piglets. The present study demonstrated the positive impact of fermented feed on the porcine microbial composition compared with a conventional feeding regimen in healthy pigs. At the end of the experiment (day 61 of the piglets’ life), the Lactobacillus prevalence decreased on average 2.4 fold in the groups fed non-fermented feed, whereas the prevalence increased on average 1.8 fold in the groups fed fermented feed. Hence, providing fermented feed prevents the decrease in Lactobacillus prevalence after weaning. This effect may help prevent digestive disorders associated with microbial changes because this period is one of the most critical regarding different infections [46]. It is known that during this age, Lactobacillus spp. in pigs normally decrease in number [37]. The Lactobacillus prevalence was also higher in vaccinated compared with non-vaccinated groups irrespective of the feed type. However, the data do not indicate whether vaccination against PCV2 leads to an increase in Lactobacillus prevalence; more experiments are required in this area. Moreover, different types of vaccines and larger experiments should be performed to better understand the possible influence of vaccination on the microbial communities. According to this study, it may be assumed that at the very least vaccination against PCV2 does not negatively affect the microbial composition within the gastrointestinal tract of pigs.

3.2. LAB, TVC, TEC and M/Y Counts in Piglets’ Faeces

Microbiological parameters of the piglet faeces (from 25- and 61-day-old piglets) are shown in Table 2 (Table S9—Differences between microbiological parameters of the piglets’ faeces between all the tested groups). In most groups (except the SV group), the LAB count was significantly lower at the end compared with the beginning of the experiment (20.1% lower in the S_nonV group; 37.9% lower in the RF_nonV group; and 25.3% lower in the RF_V group). The LAB count at the end of experiment was significantly higher in both vaccinated compared with non-vaccinated groups (26.6% for SV and 17.2% for RF_V). The LAB count was 26.3% higher in SV compared to the RF_V group at the end of the experiment. In a previous study, the faeces of pigs receiving a diet with fermented feed contained significantly fewer total bacteria and fungi, as well as coliform bacteria (including Escherichia coli) and anaerobic Clostridium perfringens counts. This phenomenon is due in part to the reduction in pH, an increase in the amount of lactic acid and other volatile fatty acids in the intestinal contents and a reduction in the number of Enterobacteriaceae [47,48]. From birth until weaning and then during the post-weaning period, the gut microbiota is dynamic and undergoes major compositional changes that are driven by age, exposure to microbes, environmental conditions and diet [49]. Many authors have described the great impact of early-life events in mammals, and particularly in pigs, on their future health. These experiences shape immune system development through changes in the pattern of microbial intestinal colonisation [50,51]. Colonisation is initiated at birth and is shaped by consumption of the sow’s milk, which provides nutritional advantages to the LAB population, building a milk-oriented microbiome that includes Bacteroidaceae and Lactobacillaceae. This composition rapidly changes after weaning when a (largely) plant-based diet is introduced [35]. The rapidly varying microbiome of young piglets seems to increase in microbial diversity and richness in the suckling phase and gradually stabilises post-weaning [35,52,53]. Our results are in agreement with Bian et al. [54], namely that members of the Lactobacillaceae became predominant on days 7, 14 and 28, but had a lower relative abundance again on day 49.

When comparing the TVC in piglets’ faeces, in all but the SV group it was significantly lower at the end of experiment compared with the beginning (9.5% reduction in the S_nonV group; 23.6% reduction in the RF_nonV group; 3.4% reduction in the RF_V group). TVC was significantly higher in the vaccinated piglets compared to the non-vaccinated piglet faeces at the end of the experiment (22.2% for SV and 13.8% for RF_V). Between the vaccinated groups, TVC was 10.0% higher in the SV compared to the RF_V group. During weaning, there is gut microbiota dysbiosis, including a loss of microbial
diversity. Studies have noted significant reductions in total bacterial number, including coliform bacteria and anaerobic C. perfringens, as well as an increase in Acetivibrio, Dialister, Orbitalis, Prevotella and Proteobacteriaceae, including E. coli [48,49,55,56]. A decrease in Lactobacillus spp. can lead to decrease in TVC. Zimmerman et al. [57] demonstrated that Lactobacillus, Bifidobacterium and Lactobacillus spp. have a positive immunomodulatory effect on vaccines in animals.

In all the groups, the TEC and Y/M counts were lower in piglets’ faeces at the end compared with the beginning of the experiment (11.9 and 5.5%, respectively, for the SnonV group; 26.1 and 44.1%, respectively, for the SV group; 7.2 and 7.9%, respectively, for the RFnonV group; 6.1 and 5.6%, respectively, for the RFV group). Both TEC and Y/M were significantly lower in the SV compared to SnonV group faeces at the end of experiment, but the opposite was true for the RFV compared to the RFnonV group. At the end of the experiment, the TEC and Y/M counts were higher in the RFV compared to the SV group (13.2 and 31.2%, respectively). Our results are in agreement with Dowarah et al. [58], who showed that fermented feed improved the number of beneficial microbes (LAB and bifidobacteria) and reduced E. coli and clostridia count, the pathogens responsible for diarrhoea, in faces. Arfken et al. [59] investigated the mutualistic relationship between yeast in the piglet gastrointestinal (GI) tract and Lactobacillus count. There was a significant reduction in the total number of fungi compared with the control group [48].

The ANOVA results indicated that there were significant treatment duration, fermented feed and vaccination main effects, as well as significant treatment duration × fermented feed, treatment duration × vaccination, fermented feed × vaccination and treatment duration × fermented feed × vaccination interactions on microbiological parameters of the pig faeces. Indeed, only the fermented feed × vaccination interaction was not significant for TVC in pig faeces.

Finally, microbiological parameters of the piglets’ faeces were varied and, in most of the cases, influenced by the analysed factors and their interaction. Considering that genera and species as well as the interaction between strains can lead changes of piglets’ growth performance, correlation between the above-mentioned parameters were calculated.

### Table 2. Microbiological parameters in faeces from 25- and 61-day-old piglets.

| Microbiological Parameters (log_{10} CFU/g) | Day | Treatments | SnonV | SV | RFnonV | RFV |
|-------------------------------------------|-----|------------|-------|----|--------|-----|
| LAB                                       | Baseline | 7.78 ± 0.03 Aa | 8.22 ± 0.04 Ab | 8.33 ± 0.05 Aa | 8.35 ± 0.06 Aa |
|                                           | 61   | 6.22 ± 0.04 Ab | 8.47 ± 0.02 Ab | 5.17 ± 0.06 Ba | 6.24 ± 0.07 Ba |
| TVC                                       | Baseline | 7.08 ± 0.02 Aa | 8.25 ± 0.05 Ab | 8.38 ± 0.07 Ab | 7.68 ± 0.07 Aa |

SnonV—non-vaccinated piglets fed with control group compound feed; SV—vaccinated piglets fed with control group compound feed; RFnonV—non-vaccinated piglets fed with fermented compound feed; RFV—vaccinated piglets fed with fermented compound feed. CFU—colony forming units; LAB—lactic acid bacteria; TVC—total viable bacteria count; TEC—total enterobacteria count; Y/M—yeast/mould count. Measurements were made at baseline—day 25, before the start of the feeding experiment—and on day 61, the end of the experiment. A,B Different uppercase letters indicate significant treatment duration-related differences (p ≤ 0.05). a,b Different lowercase letters indicate differences among treatments, comparing SnonV and SV; RFnonV and RFV (p ≤ 0.05). Data are presented as mean values ± standard error (n = 10 per group).
3.3. Piglet Blood Parameters

The piglets’ blood parameters are shown in Table 3 (Table S10—Differences between blood parameters of the piglets’ between all the tested groups). At the end of experiment, there were significantly lower ALT, T3, T4, IP, Mg, K, Ca and vitamin B12 concentrations in the SV compared with the SnonV group. However, in the SSV group, Chol, HDL-C, TP and GLU concentrations were significantly higher compared with the SnonV group. At the end of experiment, there were significantly lower ALT, HDL-C, LDL-C, TP, ALB and Fe blood concentrations in the RFV compared to RFnonV group. However, in the RFV group blood, TG and total bilirubin concentrations were significantly higher compared with the RFnonV group.

When comparing blood parameters between the vaccinated groups (SV and RFV) at the end of experiment, ALT, TG, IgG, Mg, K, Fe and total bilirubin were significantly higher in the RFV group. By contrast, HDL-C, LDL-C, TP, ALB, T3, T4 and vitamin B12 were significantly lower in the RFV compared with the SV group.

In general, blood biochemical indices reflect comprehensive functions of piglet’s nutritional metabolism, health and welfare [60]. The IgG level reflects immune status, plays important roles in the humoral immune response and controls bacterial infections in the body; it can also function to control diarrhoeal infections by binding multiple pathogenic antigens [46]. Lu et al. [59] reported that IgG and immunoglobulin M (IgM) concentrations were significantly greater and serum ALT and AST concentrations were decreased in pigs that received fermented feed ($p \leq 0.05$). The activities of the hepatic enzymes ALT and AST are key indices that reflect the acute injury of liver. The ALT blood concentration increases when the liver cell membrane is damaged. The AST content significantly increases when the liver mitochondrial membrane is impaired [60]. The blood TP concentration reflects the relationship between protein absorption in vivo and humoral immunity [60]. The hydrolysis products of glucosinolates are known to depress iodine metabolism in the thyroid gland and inhibit the synthesis of thyroid hormones T3 and T4. When these compounds, especially thiocyanates, interfere with iodine uptake, hypothyroidism and thyroid gland enlargement may ensue [46]. However, in this study the utilised rapeseed meal contained very low concentrations of erucic acid and glucosinolates (7.5–11.2 µmol/g). Hence, the influence of the above-mentioned compounds on T3 and T4 should be minimal. The fermentation process can reduce dietary anti-nutrients (phytates, glucosinolates and trypsin inhibitors) and improve the absorption and use of nutrients, including amino acids and minerals (e.g., P, Ca, Zn, Cu and Fe) [48,61]. These changes can lead to haematological, biochemical and mineral profile variations in the blood [61,62]. However, it was published that the TP concentration was increased in the blood of piglets fed fermented feed [63]. In opposition to above-mentioned findings, Min [64] reported that the TP blood concentration was not affected by the fermented feed diets. In serum samples from piglets fed with fermented feed, there were higher ALP, TP, ALB and GLU concentrations [62,65,66]. Liu et al. [15] published that piglets fed fermented feed had lower levels of serum IgG, but there was no difference in the immunoglobulin IgA and IgM serum levels. Furthermore, the serum glucose level was decreased in piglets fed fermented feed; however, TP, Chol, TG, LDL-C, ALT, AST, Ca, P and Mg were not different among the treatments [67]. Satessa et al. [68] found that fermented rapeseed meal reduced the glucose, HDL-C and LDL-C concentrations, but TP, P, AST, ALT concentrations were increased, and significant changes in blood IgG were not established. According to Czech et al. [61], the blood concentrations of Chol and TG AST in piglets fed with fermented rapeseed meal was reduced, and there was better availability of minerals.

$S_{\text{nonV}}$—non-vaccinated piglets fed with control group compound feed; $S_V$—vaccinated piglets fed with control group compound feed; $RF_{\text{nonV}}$—non-vaccinated piglets fed with fermented compound feed; $RF_V$—vaccinated piglets fed with fermented compound feed. Measurements were made at baseline—day 25, before the start of the feeding experiment—and on day 61, the end of the experiment. $A,B$ Different uppercase letters indicate significant treatment duration-related differences ($p \leq 0.05$). $A,b$ Different lowercase letters indicate differences among treatments: $S_{\text{nonV}}$ and $S_V$; $RF_{\text{nonV}}$ and $RF_V$ ($p \leq 0.05$). Data are presented as mean values (n = 10 per group).
The influence of the analysed factors and their interaction on piglets’ blood parameters is shown in Table 4. Vaccination as a separate factor did not significantly influence piglets’ blood parameters. However, the treatment duration × fermented feed interaction was significant for T3 (p = 0.038), T4 (p = 0.041) and Fe (p = 0.008) concentrations in piglets’ blood. There was a significant treatment duration × vaccination interaction on T4 (p = 0.008) and K (p = 0.007) concentrations in piglets’ blood. Finally, there was a significant fermented feed × vaccination interaction for T4 (p = 0.033), vitamin B12 (p = 0.003) and urea (p = 0.014) concentrations in piglets’ blood. All three factors were significant with regard to the TP content in piglets’ blood (p = 0.041).

3.4. Piglets’ Growth Performance

The piglets’ average FCR, ADG and the influence of analysed factors and their interaction on piglets’ growth performance parameters from day 25 to 61 are shown in Table 5. For ADG, there were no significant differences among the groups. In addition, the analysed factors as well as their interactions did not exert significant effects on piglets’ ADG. However, there were significant differences in FCR between SV and SnonV (11.5% lower in the SV group), between RFV and RFnonV (10.2% lower in the RFnonV group) and between SV and RFV (21.6% lower in the SV group). There was a significant, very strong positive correlation between FCR and TEC in piglets’ faeces (R = 0.919, p = 0.041). There were no significant correlations between the other analysed faecal microbiological parameters (LAB, TBC and Y/M count) and FCR or ADG.
Mortality and diarrhoea cases were similar in all groups throughout the experiment. The mortality of piglets in the non-vaccinated groups ($S_{\text{nonV}}$ and $RF_{\text{nonV}}$) was 2%, while mortality in the vaccinated groups ($S_V$ and $RF_V$) was 2% and 3%, respectively. There was more intense diarrhoea in the $S_{\text{nonV}}$ group at day 31 and 36. There were several diarrhoea cases in the $S_V$, $RF_{\text{nonV}}$ and $RF_V$ groups from day 28 to 46.

### Table 5. Influence of the analysed factors and their interactions on piglets’ growth performance.

| Piglets Growth Performance | Average from day 25 to 61 | Treatments |
|----------------------------|---------------------------|-------------|
|                            |                           | $S_{\text{nonV}}$ | $S_V$ | $RF_{\text{nonV}}$ | $RF_V$ |
| FCR                        | 1.56                      | 1.38         | 1.58 | 1.76 |

$S_{\text{nonV}}$—non-vaccinated piglets fed with control group compound feed; $S_V$—vaccinated piglets fed with control group compound feed; $RF_{\text{nonV}}$—non-vaccinated piglets fed with fermented compound feed; $RF_V$—vaccinated piglets fed with fermented compound feed. FCR—feed conversion ratio; ADG—average daily gain. Measurements were made at baseline—on day 25, before the start of the feeding experiment—and on day 61, the end of the experiment. Bold values indicate significant differences ($p \leq 0.05$). Data are presented as mean values ($n = 100$ per group).

The available published information about the influence of vaccination on piglets’ growth performance is varied. According to Oliver-Ferrando et al. [69], the optimal time for PCV2 vaccination is at either 3 or 6 weeks of age. In our study, piglets were vaccinated on day 25 of life. Duivon et al. [70] published that the added PCV2 valence in the vaccination protocol helps counter the negative impact of subclinical PCV2 infection on growth. Jeong et al. [71] indicated that ADG showed improvement in vaccinated compared with non-vaccinated animals. Da Silva et al. [72] compared the ADG between vaccinated and non-vaccinated animals from weaning to finishing for four commercial vaccine products. All products significantly increased ADG values. However, according to Woźniak et al. [73] data from four farms where vaccination was used, the results were similar to those from non-vaccinated farms. The authors suggested revising the vaccination protocol. The above-mentioned findings can be explained by a major PCV2 genotype shift from the predominant PCV2 genotype 2b towards 2d [74]. While the commercial vaccines that were first introduced to the US in 2006 have been highly effective in reducing clinical signs and improving production, recent studies have indicated a declining level of PCV2 prevalence and viraemia in the field. Hence, the efficiency of current vaccines against new and emerging strains, as well as new vaccine development, is crucial [75]. Vaccination against PCV2 is an important co-working agent that confers unintended benefits in the protection against the other agents [76]. Notably, the breed information is frequently omitted from experimental publications of vaccine studies, as well as environmental conditions (temperature, stocking density, etc.). These factors are very important for the further standardisation across studies before logical comparisons can be made among studies [77].
While we found differences in the ADG between different groups, the influence of vaccination on different feed groups was the opposite. Specifically, the FCR was lower in the Sv compared to the Sn group. However, the effect was the opposite in the rapeseed meal groups: FCR was lower in the RFV group compared to the RFNV group. The lowest FCR (1.38) occurred in the SV group. Notably, soya-based feed is much more expensive compared with the feed composed of local rapeseed meal. Overall, the data support the use of fermented local feedstock for piglet feeding because it provides similar growth parameters as imported soya.

3.5. Influence of Analysed Factors on Ammonia Emission

Table 6 presents the influence of the analysed factors on ammonia emission. At the end of experiment, the RFV group had the lowest ammonia emission: 58.2, 23.8 and 47.33% lower than the SnV, SV, and RFNV groups, respectively. There was lower ammonia emission in vaccinated groups at the end of the experiment: 45.2% lower in the SV compared to Sn group and 47.33% lower in the RFV compared to the RFNV group. ANOVA revealed a significant effect for all the analysed factors and their interaction on ammonia emission. Furthermore, there was a significant, very strong positive correlation between ammonia emission and Y/M count in piglets' faeces at the end of experiment (R = 0.974; p = 0.013).

Table 6. Influence of the analysed factors on ammonia emission.

| Ammonia Emission | Day | Treatments | SnV | SV | RFNV | RFV |
|------------------|-----|------------|-----|----|------|-----|
| Baseline         | 0.837 A,a | 1.172 A,b  | 1.584 A,a | 1.252 A,b |
| 61               | 1.938 B,a | 1.063 A,b  | 1.538 A,a | 0.810 B,b |

Tests of between-subject effects: influence of the analysed factors and their interactions on ammonia emission

| Treatment Duration | Fermented Feed | Vaccination | Treatment Duration × Fermented Feed | Treatment Duration × Vaccination | Fermented Feed × Vaccination | Treatment Duration × Fermented Feed × Vaccination |
|--------------------|---------------|-------------|-----------------------------------|--------------------------------|-----------------------------|-----------------------------------------------|
| SnV—non-vaccinated piglets fed with soya meal; SV—vaccinated piglets fed with soya meal; RFNV—non-vaccinated piglets fed with fermented rapeseed meal; RFV—vaccinated piglets fed with fermented rapeseed meal. Measurements were done at baseline, on day 25 before the start of the feeding experiment, and on day 61, the end of the experiment. A-B Different uppercase letters indicate significant treatment duration-related differences (p ≤ 0.05). a-b Different lowercase letters indicate differences among treatments (p ≤ 0.05). Bold values indicate significant differences (p ≤ 0.05). Data are presented as the mean values (n = 3). |

There has been no information published about the influence of vaccination on ammonia emission; most of the published studies have focussed on dietary aspects. Yi et al. [37] and Lee et al. [78] reported that protected organic acids used for weanling pigs reduce faecal ammonia. Nguyen et al. [79] concluded that diets with probiotics mixture decreased pigs’ ammonia emission. According to Wang et al. [51], diets with fermented feed ingredients tended to decrease ammonia emissions, but this effect was not statistically significant. According to Bindas et al. [80], ammonia in the faeces of experimental animals fed with fermented feed was significantly lower compared with the control animals. Reducing ammonia emissions by changing the dietary composition is considered economical and feasible because it can improve nitrogen utilisation and, consequently, reduce ammonia emissions [53]. Lactobacilli-based feed fermentation decreases the emissions of total organic carbon and ammonium [67]. Finally, many factors can contribute to ammonia emission on pig farms. Our data indicate that vaccination as a factor should be considered, as well as microbiological parameters of the piglets’ faeces. Indeed, we found a very strong correlation between ammonia emission and Y/M count in piglets’ faeces.
4. Conclusions

Fermented feed had a positive impact on the amount of Lactobacillus during the post-weaning period of pigs. In addition, vaccination had no negative impact on microbial communities. There was a higher Lactobacillus prevalence in vaccinated compared with non-vaccinated groups, as well as a higher viable LAB count in faeces from both vaccinated groups (SV and RFV) at the end of experiment. There were no significant differences in ADG between piglets’ groups. There were differences in FCR: 11.5% lower in the SV compared with the SnonV group, 10.2% lower in the RFnonV compared with the RFV group, and 21.6% lower in the SV compared with the RFV group. There were a significant, very strong positive correlations between FCR and TEC in piglets’ faeces (R = 0.919, p = 0.041) and between ammonia emission and Y/M count in piglets’ faeces at the end of experiment (R = 0.974, p = 0.013). The lowest ammonia emission was in the RFV group section. Vaccination as a separate factor did not significantly influence piglets’ blood parameters. Overall, by changing from an extruded soya to cheaper rapeseed meal and applying the fermentation model with the selected LAB combination, it is possible to feed piglets without any undesirable changes in health and growth performance, as well as in a more sustainable manner. However, to evaluate the influence of vaccination and its interaction with other parameters (feed, piglet age, breed, etc.) on piglets’ parameters, additional studies should be performed and methods should be standardised so that the results may be compared.
